# **Preface**

#### (Textbook Access (pdf))

This document serves as a supplementary guide to C++ from Control Structures Through Objects by Tony Gaddis. While the original text is geared towards beginners, this guide aims to assist those who already have programming experience, possibly in other languages.

To streamline the content and focus on aspects that are unique or nuanced in C++, this guide omits Chapters I and II of the original text. Instead, you will find a concise overview of the following foundational topics:

- Language Features
- The complier
- Boilerplate Code Structure
- Commenting Practices
- Data Types, Modifiers, Qualifiers, and Inference
- Type introspection
- Operators and Special Symbols
- The Using Directive
- Scope
- Preprocessor Directives
- Standard Input/Output Techniques

Please note that basic elements like variables and arithmetic operations are not covered in this guide, under the assumption that readers are already familiar with these core computing concepts.

# C++ from control structures through objects

## 1 The C++ Language

C++ is a high-level, general-purpose programming language that was developed as an extension of the C programming language. Created by Bjarne Stroustrup, the first version was released in 1985. C++ is known for providing both high- and low-level programming capabilities. It is widely used for developing system software, application software, real-time systems, device drivers, embedded systems, high-performance servers, and client applications, among other things. C++ is praised for its performance and it's used for system/software development and in other fields, including real-time systems, robotics, and scientific computing.

#### 1.1 Key Features

- Object-Oriented: C++ supports Object-Oriented Programming (OOP), which allows for better organization and more reusable code. Concepts like inheritance, polymorphism, and encapsulation are available.
- **Procedural:** While C++ supports OOP, it also allows procedural programming, just like its predecessor C. This makes it easier to migrate code from C to C++.
- Low-level Memory Access: Like C, C++ allows for low-level memory access using pointers. This is crucial for system-level tasks.
- STL (Standard Template Library): C++ comes with a rich set of libraries that include pre-built functions and data types for a variety of common programming tasks, from handling strings to performing complex data manipulations.
- **Strongly Typed:** C++ has a strong type system to prevent unintended operations, although it does provide facilities to bypass this.
- **Performance:** One of the most significant advantages of C++ is its performance, which is close to the hardware level, making it suitable for high-performance applications.
- Multiple Paradigms: In addition to procedural and object-oriented programming, C++ also supports functional programming paradigms.

## 2 The Compiler

Unlike interpreted languages like Python or JS, C++ is a compiled language. The C++ compiler is a toolchain that takes C++ source code files and transforms them into executable files that a computer can run. The process involves several stages to get from human-readable C++ code to machine code that a CPU can execute.

Here's a general breakdown of the C++ compilation process:

#### 2.1 Preprocessing

In this stage, the **preprocessor** takes care of directives like #include, #define, and #ifdef. It replaces macros with their actual values and includes header files into the source code. The output of this stage is an expanded source code file.

- Macro Replacement: Replace macros with their respective values.
- File Inclusion: Include header files specified by #include directives.
- Conditional Compilation: Code between #ifdef and #endif (or related preprocessor conditionals) is included or excluded based on the condition.

#### 2.2 Lexical Analysis

The expanded source code is then tokenized into a sequence of tokens (keywords, symbols, identifiers, etc.). This stage is known as lexical analysis or scanning. The lexer converts the character sequence of the program into a sequence of lexical tokens.

#### 2.3 Syntax Analysis

The sequence of tokens is then parsed into a syntax tree based on the grammar rules of the C++ language. This stage is known as syntax analysis or parsing. The parser checks whether the code follows the syntax rules of C++ and constructs a syntax tree which is used in the subsequent stages of the compiler.

#### 2.4 Semantic Analysis

Semantic rules like type-checking, scope resolution, and other language-specific constraints are verified at this stage. For example, it ensures that variables are declared before use, that functions are called with the correct number and types of arguments, etc.

#### 2.5 Intermediate Code Generation

The syntax tree or another intermediate form is then converted into an intermediate representation (IR) of the code. This is often a lower-level form of the code that is easier to optimize.

#### 2.6 Code Optimization

The compiler attempts to improve the intermediate code so that it runs faster and/or takes up less space. This can involve removing unnecessary instructions, simplifying calculations, etc.

#### 2.7 Code Generation

The optimized intermediate representation is then translated into assembly code for the target platform. The assembly code is specific to the computer architecture and can be assembled into machine code.

#### 2.8 Assembling

The assembly code is then processed by an assembler to produce object code, which consists of machine-level instructions.

#### 2.9 Linking

Finally, the object code is linked with other object files and libraries to produce the final executable. The linker resolves all external symbols, combines different pieces of code, and arranges them in memory to create a standalone executable.

#### 2.10 Complier Options

For linux users that are not using IDES, we are free to choose which complier to use when building C++ code. The most common compliers are:

- g++ (GCC (GNU Compiler Collection)): GCC is the de facto standard compiler for Linux. It supports multiple programming languages, but you'll most commonly use g++ for compiling C++ code.
  - Compile a program: g++ source.cpp -o output
  - Compile and link multiple files: g++ source1.cpp source2.cpp -o output
  - Use C++11 or later standards: g++ -std=c++11 source.cpp -o output
- Clang: Clang is known for its fast compilation and excellent diagnostics. It's part of the LLVM project and is fully compatible with GCC.
  - Compile a program: clang++ source.cpp -o output
  - Compile and link multiple files: clang++ source1.cpp source2.cpp -o output
  - Use C++11 or later standards: clang++ -std=c++11 source.cpp -o output
- Intel C++ Compiler: The Intel C++ Compiler (icpc) is focused on performance and is optimized for Intel processors, although it can also generate code for AMD processors.
  - Compile a program: icpc source.cpp -o output
  - Compile and link multiple files: icpc source1.cpp source2.cpp -o output
  - Use C++11 or later standards: icpc -std=c++11 source.cpp -o output

#### 2.11 Header Files

Header files are generally not included in the command line arguments when compiling. However, we can specify to the complier where to look for them:

```
g++ -I path/to/headerfiles/ main.cpp -o main
g++ -isystem path/to/system/headerfiles/ main.cpp -o main
```

# 3 Preliminaries: A Quick Tour of C++ Fundamentals

#### 3.1 Boilerplate

We will begin with a examination of the boilerplate c++ code that will serve as an entry to most programs.

```
#include <iostream>
#include <iomanip>

int main(int argc, char argv[]){

return 0
}
```

Every C++ program has a primary function that must be named main. The main function serves as the starting point for program execution. It usually controls program execution by directing the calls to other functions in the program.

The includes at the top of the program are common in a c++ program, they are *iostream* and *iomanip*. These library's allow us to recieve input via the input stream, as well as to output information via the output stream. Whereas *iomanip* allows us to preform varies manipulations on such streams.

#### 8 Note:

return 0 is important in our main function, this is because the *int* you see in front of *main* declares which data type the function must return. Note that you may also see **EXIT\_SUCCESS** or **EXIT\_FAILURE**. These, along with any other integer values are suitable return types for the main function.

#### 3.2 The main function

The main() function serves as the entry point for a C++ program. When you execute a compiled C++ program, the operating system transfers control to this function, effectively kicking off the execution of your code.

In C++, you generally cannot execute code like std::cout << "Hello, world!"; outside of a function body. Code execution starts from the main() function, and any executable code outside of a function is not valid C++ syntax. However you can declare and initialize variables, functions etc. Note that if you try to assign a variable you will get an error.

#### 3.3 Comments

In order to display comments in our C++ program, we use // (double forward slashes)

```
#include <iostream>
#include <iomanip>

int main() {

// This is a comment
/* This is a Multi Line Comment */

return EXIT_SUCCESS;
}
```

#### 3.4 Data Types, Modifiers, Qualifiers, Inference

#### Integer type

- int (4 bytes on most systems)
- **short** (2)
- **short int** (2)
- long (4 or 8 bytes depending on system)
- long long (>=8)
- long int (4 | 8)
- long long int (>=8)

### Character Types

- char (1 byte)
- wchar\_t (2 or 4 bytes)
- char16\_t (2 bytes)
- char32 t (4 bytes)

#### Floating point types

- float (4 bytes) (always signed)
- double (8 bytes) (always signed)
- long double (8, 12, or 16 bytes) (always signed)

#### Boolean Type

• bool (1 byte)

#### Void type

• void (No storage)

#### String type

• std::string (Depends on length) <sup>a</sup>

<sup>a</sup>must include <string>

# Fixed-Width Integer Types: (defined in <cstdint>)

- int8\_t (1 byte) uint8\_t (1 byte)
- int16\_t (2 bytes) uint16\_t (2 bytes)
- int32\_t (4 bytes) uint32\_t (4 bytes)
- int64 t (8 bytes) uint64 t (8 bytes)

#### Type Qualifiers:

- const (No additional storage) <sup>a</sup>
- volatile (No additional storage)
- Inference
  - auto (Depends on the type it infers)
  - decltype (Depends on the type it infers)

 $<sup>^</sup>a\mathrm{Typically},$  symbolic constants are denoted will all capital letters

Symbolic constants should be identified will capital letters, although this is just convention.

#### 3.5 Creating strings without the STL

To create a string **without** using the C++ standard library (STL), we can create an array of characters. For this we have two options.

```
int main() {

// Option I
char mystring[] = "hello world";

// Option II
const char* mystring = "Hello World";
return 0;
}
```

Note regarding the first option: simply declaring mystring without any sort of initialization will through an error. This is due to the way arrays behave in c++, more on this later.

For the second option, we declare a pointer of characters. Note that although it is declared constant, it is legal to change the value of mystring. We can't change the characters that are pointed at, but we can change the pointer itself.

Furthermore, It is worth pointing out that there is a third way of making a string without use of the STL, it is as follows.

```
#include <iostream>
int main(int argc, char agrv[]){

char const* mystring = "Hello world";

return 0;
}
```

The const modifier in C++ binds to the element that is immediately to its left, except when there is nothing to its left, in which case it binds to the element immediately to its right.

#### Note:

Usage of the asterisk will be discussed in a later section. This concept is known as the "pointer"

#### 3.6 Retrieve size

To retrieve the size of a variable or data type we can use the size of () function.

```
#include <iostream>
using std::cout;
using std::endl;

int main() {
    int a = 12;
    size_t b = sizeof(a);
    cout << b << endl

return 0;
}</pre>
```

#### 2 Note:

We use size\_t for the type of a variable that will house the size (in bytes) of some other variable

#### 3.7 Retrieve type

To retrieve the type of a variable we can use the type id().name() function. Note that this function is part of the <type info> library

```
#include <iostream>
#include <typeinfo>
using std::cout;
using std::endl;

int main(){

int a = 12;

cout << typeid(a).name() << endl;

return 0

}</pre>
```

#### 3.8 Exponential Notation

In C++, you can use exponential notation to represent floating-point numbers. This is particularly useful when you're dealing with very large or very small numbers. In exponential notation, a floating-point number is represented as a base and an exponent, often separated by the letter e or E.

```
#include <iostream>
   int main(int argc, char argv[]){
       double num1 = 1.23e4;
       double num2 = 1.23e-4;
       double num3 = 5e6;
       double num4 = 5e+6; // The same as the previous example (num3)
       // Outputting the numbers
       std::cout << "num1: " << num1 << std::endl; // Output should be 12300
10
       std::cout << "num2: " << num2 << std::endl; // Output should be 0.000123
       std::cout << "num3: " << num3 << std::endl; // Output should be 5000000
12
       return 0;
13
   }
14
```

#### **8** Note:

Note that while you can use exponential notation for readability and convenience, the variables themselves will store the actual values. For example, num1 will actually store 12300.0, not 1.23e4.

#### 3.9 Type Conversion

**Concept 1:** When an operator's operands are of different data types, C++ will automatically convert them to the same data type. C++ follows a set of rules when performing mathematical operations on variables of different data types.

#### Data Type Ranking:

- 1. long double
- 2. double
- 3. float
- 4. unsigned long long int
- 5. long long int
- 6. unsigned long int
- 7. long int
- 8. unsigned int
- 9. int
- Rule 1: Chars, shorts, and unsigned shorts are automatically promoted to int.
- Rule 2: The lower-ranking value is promoted to the type of the higher ranking value.

#### 3.10 Integer Division

Concept 2: When you divide an integer by another integer in c++, the result is always an integer.

#### 3.11 Overflow/Underflow

**Concept 3:** When a variable is assigned a value that is too large or too small in range for that variable's data type, the variable overflows or underflows. Ty

#### 3.12 Type Casting

**Concept 4:** Type Casting allows you to perform manual data type conversion. The general syntax of a type cast expression is:

```
static_cast<Type>(value)
```

Consider the example

```
#include <iostream>
int main(int argc, char argv[]){
   int a = 12.12;
   a = static_cast<float>(a);

return 0;
}
```

Even though you are casting a to a float, the variable a stays as an integer because you are assigning the result back into a, which was originally declared as an integer. In C++, you can't change the data type of a variable once it's declared; you can only temporarily alter how it behaves through casting.

#### 3.13 C-style Casts

It is worth noting that static\_cast is not our only option. There is the standard C-style cast:

```
1 float a = 12.2;
2 cout << (int) a;</pre>
```

#### 3.14 The Using Directive

The using namespace directive allows you to use names (variables, types, functions, etc.) from a particular namespace without prefixing them with the namespace name. For example:

```
#include <iostream>
#include <iomanip>
using namespace std;

int main(){
    cout << "Hello World" << endl;
    return 0;
}</pre>
```

Here, cout and endl are part of the std namespace, and the using statement allows us to use them without the std:: prefix. This is convenient but can lead to name clashes if multiple namespaces have elements with the same name. Instead we can do:

```
#include <iostream>
#include <iomanip>
using std::cout;
using std::endl;

int main(){
    cout << "Hello World" << endl;
    return 0;
}</pre>
```

We can also use this directive to create an alias for a type. This is especially useful for simplifying complex or templated types:

```
#include <iostream>
   #include <iomanip>
   using std::cout;
   using std::endl;
   using myint = int;
   int main() {
9
        myint a = 12;
10
        cout << a << endl;</pre>
11
12
        return EXIT_SUCCESS;
13
   }
14
```

#### 3.15 Variable Declaration

Declaring a variable means telling the compiler about its name and type, but not necessarily assigning a value to it. At the time of declaration, memory is allocated for the variable. You may or may not initialize it immediately. Here are some examples:

Note that variables of built-in types declared without initialization will have an undefined value in C++ until you explicitly assign a value to them. However, global and static variables are automatically initialized to zero if you do not explicitly initialize them.

#### 3.16 Multiple Declaration

In c++, we can declare multiple variables on a single line:

```
ı int a,b,c
```

#### 3.17 Initialization

We can also combine declaration and assignment together:

```
1 int a = 12;
```

#### 3.18 Multiple Initialization

We can declare and assign multiple variables on a single line with:

```
1 int a = 5, b = 10, c = 15;
```

#### 3.19 Direct Initialization

```
1 int a(5);
```

In this case, the variable a is directly initialized with the value 5 using parentheses. This is known as "direct initialization." Direct initialization is generally straightforward and efficient.

#### 3.20 List Initialization

```
int a{5};
```

Here, the variable b is initialized with the value 10 using curly braces. This is called "list initialization" or "uniform initialization" and is available starting with C++11. One of its advantages is that it prevents narrowing conversions (e.g., from double to int without a cast).

List initialization has the benefit of disallowing narrowing conversions, making it somewhat safer. For example, int x3.14; would cause a compiler error, while int x=3.14; would compile with a possible warning, depending on the compiler settings.

#### 3.21 Copy Initialization

```
1 int a = 5;
```

In this style, known as "copy initialization," the variable c is initialized with the value 15 using the = operator. This is one of the most commonly used forms of initialization.

#### 3.22 Assignment

Assignment refers to the action of storing a value in a variable that has already been declared. This is done using the assignment operator =.

#### 3.23 Multiple Assignment

We can assign multiple variables on a single line:

```
1 a = 5, b = 10, c = 15;
```

# 4 Symbols

#### 4.1 Parentheses

Parentheses are used for several purposes:

- Function calls: myFunction(arg1, arg2)
- Operator precedence: (a + b) \* c
- Casting: (int) myDouble
- Control statements: if (condition) ...

#### 4.3 Braces

Braces Braces define a scope and are commonly used for:

- Enclosing the bodies of functions, loops, and conditional statements.
- Initializer lists.
- Defining a struct or class.

#### 4.5 Semi Colon

Semi colons are used for:

- Terminate statements
- Separate statements within a single line
- After class and struct definitions.

#### 4.2 Brackets

Square brackets are generally used for:

- Array indexing: myArray[2] = 5;
- Vector and other container types also use this syntax for element access.

#### 4.4 Angle Brackets

Angel Brackets are used in:

- Template declaration and instantiation: std::vector<int>
- Shift operators:  $a \ll 2$ ,  $b \gg 2$
- Comparison: a < b, a > b

#### 4.6 Colon

Colons are used for:

- Inheritance and interface implementation: class Derived: public Base ...
- Label declaration for goto statements.
- Range-based for loops (C++11 and above): for (auto i : vec)
- Bit fields in structs: struct S unsigned int b: 3;;
- To initialize class member variables in constructor initializer lists.

#### 4.7 Comma

Commas are used for:

- Separate function arguments
- Separate variables in a declaration: int a = 1, b = 2;
- Create a sequence point, executing left-hand expression before right-hand expression: a = (b++, b + 2);

#### 4.9 Hash

Hashes are used for preprocessor directives

#### 4.8 Ellipsis

Ellipsis are used for:

• Variable number of function arguments (C-style): void myFunc(int x, ...)

#### 5 Preprocessor Directives

C++ preprocessor directives are lines in your code that start with the hash symbol (#). These directives are not C++ statements or expressions; instead, they are instructions to the preprocessor about how to treat the code. Here's an overview of some of the most commonly used preprocessor directives in C++:

#### 5.1 #include

Used to include the contents of a file within another file. This is commonly used for including standard library headers or user-defined header files.

```
#include <iostream>
#include "myheader.h"
```

#### 5.2 #define

Used for macro substitution. It can define both simple values and more complex macro functions.

```
#define PI 3.14159 // Defines PI as 3.14159.
#define SQUARE(x) ((x)*(x)) // Defines a macro that squares its argument.
```

#### 5.3 #undef

Undefines a preprocessor macro, making it possible to redefine it later.

```
1 #undef PI
```

#### 5.4 #ifdef, #ifndef, #else, #elif, #endif

These are used for conditional compilation.

```
#ifdef DEBUG // Compiles the following code only if DEBUG is defined.
#ifndef DEBUG // Compiles the following code only if DEBUG is not defined.
#else // Provides an alternative if the preceding #ifdef or #ifndef fails.
#elif // Like else if in standard C++, allows chaining conditions.
#endif // Ends a conditional compilation block.
```

#### 5.5 #if

Like #ifdef, but it allows for more complex expressions.

#### 5.6 #pragma

Issues special commands to the compiler. These are compiler-specific and non-portable.

```
#pragma once
/* Ensures that the header file is included only once during compilation.
This is an alternative to the traditional include guard (#ifndef, #define,

#endif). */
```

#### 5.7 #error

Generates a compile-time error with a message.

```
#error "Something went wrong" // Produces a compilation error with the given

→ message.
```

#### 5.8 #line

Changes the line number and filename for error reporting and debugging.

# 6 Input/Output

This section will discuss the input/output stream, and objects defined in the iostream and iomanip headers.

#### 6.1 iostream

The <iostream> header file in C++ defines classes that provide functionalities for basic input-output operations. These classes are part of the C++ Standard Library and offer a high-level interface for I/O. The primary classes defined by <iostream> are:

- **istream:** Input Stream class. Objects of this class are used for input operations. The most commonly used object is cin.
- **ostream:** Output Stream class. Objects of this class are used for output operations. The most commonly used object is cout.

#### 6.2 Output

We can output data to the stream buffer with the cout object, here is an example:

```
#include <iostream>
using std::cout;
using std::endl;

int main(int argc, char argv[]){

cout << "Hello World" << endl;

return 0;
}</pre>
```

#### 6.3 Input

We can read data from the input stream and store in a variable with the cin object, here is an example:

```
#include <iostream>
using std::cin;
using std::cout;
using std::endl;

int main(int argc, char argv[]){
   int a;
   cout << "Input: " << endl;
   cin >> a;
   return 0;
}
```

#### 6.4 IO Manipulators

In C++, input/output (I/O) manipulators are objects that are used for controlling the formatting and behavior of streams. These manipulators allow you to change the way data is presented when outputting to a stream (like cout) or read when inputting from a stream (like cin).

Here are some common manipulators:

• std::endl: Inserts a newline character into the output sequence os and flushes it <sup>1</sup>

```
std::cout << "Hello World" << std::endl;
```

• std::flush Explicitly flushes the output buffer. <sup>2</sup>

```
std::cout << "Hello World" << std::flush;
```

• std::setw(n) Sets the field width for the next insertion operation. <sup>3</sup>

```
std::cout << std::setw(10) << 77 << endl;
// Output will be " 77"</pre>
```

• std::setfill(char) Sets the fill character for the std::setw manipulator. <sup>4</sup>

```
std::cout << std::setw(10) << std::setfill('_') << 77 << endl;
// Output will be "_____77"</pre>
```

• std::setprecision(n) Sets the decimal precision for floating-point output. n should be one more than the required rounding, this is because n specifys how many significant figures to include. Thus including any numbers before the decimal. <sup>5</sup>

**Note:** once specified setprecision will be persistent throughout the rest of the program. This is also true when used in conjunction with std::fixed

```
std::cout << std::setprecision(4) << 3.14159; // 3.142
```

<sup>&</sup>lt;sup>1</sup>Defined in <ostream> which is included automatically with <iostream>

 $<sup>^2</sup>$ Refer to 1

 $<sup>^3\</sup>mathrm{Defined}$  in  $<\!\mathrm{iomanip}\!>$ 

 $<sup>^4\</sup>mathrm{Refer}$  to 3

 $<sup>^5\</sup>mathrm{Refer}$  to 3

• std::fixed: Use fixed-point notation. Works in conjunction to setprecision, allowing you to not have to account for digits before the decimal. <sup>6</sup>

```
std::cout << std::fixed << std::setprecision(3) << 3.14159;
// 3.142</pre>
```

• std::scientific: Use scientific notation for floating-point numbers. <sup>7</sup>

```
std::cout << std::scientific << 0.00000014159;
// 1.415900e-07</pre>
```

• std::skipws and std::noskipws: These control whether leading whitespaces are skipped when performing input operations. <sup>8</sup>

```
char a,b;
std::cin >> std::noskipws >> a >> b;
```

• std::boolalpha and std::noboolalpha: These allow you to output bool values as true or false instead of 1 or 0.  $^9$ 

```
1 std::cout << boolalpha << true; // true
```

• std::showpos and std::noshowpos: Show the positive sign for non-negative numerical values. <sup>10</sup>

```
1 std::cout << std::showpos << 12; // +12
```

- std::dec Use decimal base for formatting integers.
- std::hex Use hexadecimal base for formatting integers.
- std::oct Use octal base for formatting integers.
- std::showbase Show the base when outputting integer values in octal or hexadecimal.
- **std::showpoint** Show trailing zeros for floating point numbers.
- std::uppcase Convert letters to uppercase in certain format specifiers (like hex or scientific)
- std::internal This flag will right-align the number, but the sign and/or base indicator (if any) are kept to the left of the padding. Note that this function is used in conjunction with std::setw
- std::right Right justify output, used in conjunction with std::setw
- std::left Left justify output, used in conjunction with std::setw

<sup>&</sup>lt;sup>6</sup>Defined in <ios>, which is automatically included with <iostream>

 $<sup>^7\</sup>mathrm{Refer}$  to 6

 $<sup>^8\</sup>mathrm{Refer}$  to 6

 $<sup>^9\</sup>mathrm{Refer}$  to 6

 $<sup>^{10}\</sup>mathrm{Refer}$  to 6

#### 6.5 std::setiosflags

The setiosflags function in C++ allows you to set various format flags defined in the ios base class.

```
std::cout << std::showpos << std::scientific << 12.128; // +1.212800e+01
// Instead...
std::cout << std::setiosflags(std::ios::showpos | std::ios::scientific) << 12.128;</pre>
```

From the manipulators listed in the previous section, only those from the following list can be used with std::setiosflags:

- std::dec: Use decimal base for formatting integers.
- std::hex: Use hexadecimal base for formatting integers.
- std::oct: Use octal base for formatting integers.
- **std::internal**: This flag will right-align the number, but the sign and/or base indicator (if any) are kept to the left of the padding.
- std::right: Right justify output.
- std::left: Left justify output.
- std::showbase: Show the base when outputting integer values in octal or hexadecimal.
- **std::skipws**: Skip initial whitespaces before performing input operations. (This is more relevant for input streams)
- **std::boolalpha**: Output bool values as true or false instead of 1 or 0.
- std::showpos: Show the positive sign for non-negative numerical values.

#### 6.6 Escape Sequences

Escape sequences are used to represent certain special characters within string literals and character literals.

The following escape sequences are available:

Escape Sequence	Description
\'	single quote
\"	double quote
\?	question mark
\\	backslash
\a	audible bell
\b	backspace
\f	form feed - new page
\n	line feed - new line
\r	carriage return
\t	horizontal tab
\v	vertical tab

#### 6.7 User Input With Strings

**Remark.** The concepts seen 3.5 in which we create a const char\* to house a string is not a viable option for user input. However, we can do:

```
#include <iostream>
int main(int argc, char argv[]){

char a[100];
cout << "Enter something: ";
cin >> a;

return 0;
}
```

#### Note:

In modern C++ code, using std::string is generally preferred over raw character arrays for easier management and better safety.

There is a problem that occurs when collecting string data from the user with the cin object, anything typed after a whitespace will be ignored. To circumvent this, we can use **std::getline**. Note that using this method will only work for std::string objects. Using this function with const char\* or char identifier[] will not work.

The general syntax for std::getline is:

```
std::getline(input_stream, string_variable, delimiter);
```

#### Note:

The delimiter parameter is optional, it signifies the delimiter character up to which to read the line. The default is  $'\n'$ 

```
#include <iostream>
#include <string>

int main(int argc, char argv[]){

std::string a;
cout << "Enter Something: "; // FirstName LastName
std::getline(cin, a);

cout << a; // Johnny Appleseed

return 0;
}</pre>
```

#### 6.8 User input with characters

The method outlined above is highly effective for obtaining input that goes into std::string containers. However, it falls short when you try to use it to collect a single character (char) from the user.

For this scenario, we use the built in cin method **get**. The get member function reads a single character from the user, including whitespace.

This function can be called in one of two ways:

```
char ch;
ch = std::cin.get();
// OR
char ch;
std::cin.get(ch);
```

#### 6.9 Mixing cin and cin.get

One problem that occurs when using the cin.get() member function is when we attempt to combine both cin and cin.get. For example:

```
int num;
char ch;

std::cout << "Enter a number: ";
std::cin >> num;

std::cout << "\nEnter a character: ";
std::cin.get(ch)</pre>
```

If you run this code, you will notice a problem. The problem is that the cin.get doesn't give the user a chance to input a character, it immediately stores the proceeding cin's '\n'

To solve this problem, we can use another of the cin objects member functions named **ignore**. The cin.ignore function tells the cin object to skip one or more characters in the keyboard buffer. Here is its general form:

```
std::cin.ignore(n:int,c:char)
```

Where n tells cin to skip n number of characters, or until the character c is encountered. If no arguments are used, cin will skip only the very next character.

## 7 Operators

#### 7.1 Arithmetic Operators

- + (Addition)
- - (Subtraction)
- \* (Multiplication)
- / (Division)
- % (Modulus)

#### 7.3 Logical Operators

- && (Logical AND)
- || (Logical OR)
- ! (Logical NOT)

#### 7.5 Assignment Operators

- $\bullet = (Assignment)$
- + = (Addition assignment)
- -= (Subtraction assignment)
- \* = (Multiplication assignment)
- / = (Division assignment)
- % = (Modulus assignment)
- & = (Bitwise AND assignment)
- | = (Bitwise OR assignment)
- $\wedge = (Bitwise XOR assignment)$
- <<= (Left shift assignment)
- >>= (Right shift assignment)

#### 7.8 Scope Resolution Operator

• :: (Two Colons)

#### 7.2 Relational Operators

- == (Equal to)
- ! = (Not equal to)
- < (Less than)
- > (Greater than)
- <= (Less than or equal to)
- >= (Greater than or equal to)

#### 7.4 Bitwise Operators

- & (Bitwise AND)
- | (Bitwise OR)
- ∧ (Bitwise XOR)
- $\sim$  (Bitwise NOT)
- << (Left shift)
- >> (Right shift)

# 7.6 Increment and Decrement Operators

- ++ (Increment)
- -- (Decrement)

#### 7.7 Pointers and References

- & (Address-of Operator) (Also used for references)
- \* (Indirection Operator)

#### **8** Note:

The C++ does not support exponents without the use of an external library (cmath), when using the pow function, the arguments should be doubles, and the result should be stored in a double

#### 8 Random Numbers

The C++ library has a function, named **rand()**, that you can use to generate random numbers. In order to use this function, we must include the library <cstdlib> ("C Standard Library"), the general syntax for rand looks like:

```
#include <cstdlib>
int y = rand();
```

However, usage of the rand function is not truly random, if we run the program many times, we will always get the same "random" numbers. In order to truly randomize the results, we must use the srand(n:unsigned int) function. Where n acts as a seed value for the algorithm. By specifying different seed values, rand() will generate different sequences of random numbers.

A common practice for getting unique seed values is to call the **time** function, which is part of the standard library. The **time** function returns the number of seconds that have elapsed since midnight, January 1, 1970. The **time** function requires the <ctime> header file, and you pass 0 as an argument to the function.

```
#include <iostream>
#include <cstdlib>
#include <ctime>

int main(int argc, char *argv[]){

unsigned int seed = time(0);
srand(seed);

std::cout << rand() << std::endl;
std::cout << rand() << std::endl;
return EXIT_SUCCESS;
}</pre>
```

To limit the range of possible random numbers, we must do something like this:

```
min_value + (rand() % (max_value - min_value + 1)); // [min, max]
min_value + (rand() % (max_value - min_value)); // (min, max)
```

To set a custom range for double variables, we can do:

```
1 min_value + (rand() / (RAND_MAX / (max_value - min_value)));
```

Where max\_value and min\_value are both doubles, and RAND\_MAX is a constant defined in the cstdlib header.lib header.

# 9 Conditionals (Decision Structure)

The syntax for the c++ if statement is as follows:

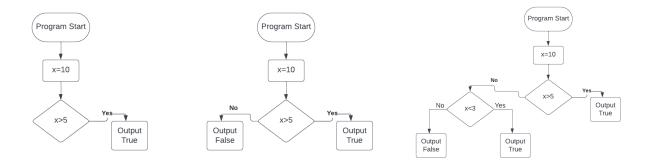

```
// Single
   for (condition){
        statements;
   }
   // Equivalent Forms (Single)
   for (condition)
        statement;
   // Double
11
   for (condition){
        Statements;
13
   }else {
        statements;
15
   }
16
17
   // Equivalent Forms (Double)
   for (condition)
19
        statement;
20
   else
21
22
        statement;
   // Multiple
24
   for (condition){
        statements
26
   }else if (condition){
28
        statements;
   }else {
       statements;
30
32
   // Equivalent Forms (Multiple)
   if (condition)
34
        statement;
35
   else if (condition)
36
        statement;
37
   else
38
        statement
39
40
```

#### **8** Note:

logical connectives have been discussed in 7.3. It is advised you review them, these operators may allow you to create **compound conditional statements** 

#### 9.1 Decision Structure Flowchart

In the context of decision structures in programming, flowcharts are particularly useful for illustrating the conditional branches that a program may follow. Below is an example of a basic flowchart.

#### 9.2 The Conditional Operator (Ternary)

**Concept 5:** You can use the **conditional operator** to create short expressions that work like if/else statements. The general syntax is as follows:

```
1 (condition)? Statement_if_true: statement_if_false
```

For example:

#### 9.3 Switch

Concept 6: The switch statement lets the value of a variable or an expression determine where the program will branch. IMPORTANT: Switch can **ONLY** be used for integers or characters

The general syntax for the switch statement is as follows:

```
switch (value){
case some_case:
statements;
break

case some_other_case:
statements;
break

default:
cout << "Cases not matched";
}</pre>
```

#### **8** Note:

With switch, if we have a default block, it is important that we have a **break** statement in each case block, say a case is matched and we enter into the block, once the program exits the case block, it will continue on with the rest of the cases. Thus, the default will be triggered.

Here is an example of switch:

```
const int x = 10;
2
   switch (x) {
3
        case 5:
             std::cout << "5";
5
             break
        case 10:
             std::cout << "10";
9
10
        default:
11
             std::cout << "No Match";</pre>
12
   }
13
```

#### **8** Note:

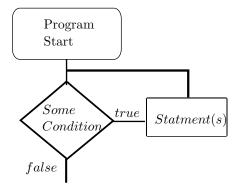

The switch statement in C++ expects constant integral expressions for its case labels. In other words, the value for each case must be known at compile time and cannot be a variable or an expression that involves variables.

# 10 The While Loop

The general syntax for the C++ while loop is as follows:

```
while (expression)
statement;
// or
while (expression) {
statements;
}
```

Let's take a look a flowchart that describes a while loop:

#### **8** Note:

The while loop is know as a **pretest loop**, this is because its nature of testing the condition before each iteration

# 11 The Do-While Loop

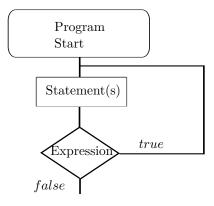

Concept 7: The do while loop is a posttest loop which means its expression is tested after each iteration. Below is the general syntax for the do-while loop in C++:

```
do
statement
while (expression);

// or

do {
s statements;
y } while (expression);
```

Let's take a look at a simple flowchart that describes this concept.

# 12 The for loop

Concept 8: There are two types of loops, conditional loops and count-controlled loops. The for loop demonstrates a count-controlled loop, this type of loop is ideal for performing a known number of iterations.

The general syntax for the for loop is as follows

```
for (initialization; test; update)
statement;

// or

for (initialization; test; update) {
statements;
}
```

# **8** Note:

It is valid syntax to execute more than one statement in the initialization expression and the update expression. Additionally, the initialization stage of the for loop declaration if has already been preformed or if no Initialization is needed.

below is an example of a for loop without the initialization stage.

```
int x=0;
for (; x < 10; ++x) {
    statements;
}
</pre>
```

You may also omit the update stage of the for loop header if it will be preformed elsewhere in the loop body. In fact, you can even go as far as omitting all three expressions in loops parenthesis.

# 13 Using Files for Data Storage

**Concept 9:** When a program needs to save data for later use, it writes the data in a file. The data can then be read from the file at a later time.

### 13.1 File Access Methods

There are two general ways to access data stored in a file: sequential access and direct access. When you work with sequential-access file, you access data from the beginning of the file to the end of the file.

When you work with a *direct-access file*, you can jump to any piece of data within the file without reading the data that comes before it.

# 13.2 Setting up a program for file input/output

In order for us to use file stream objects, we must include <fstream>.

#include <fstream>

# 13.3 File Stream Objects

In order for a program to work with a file on the computer's disk, the program must create a file stream object in memory. A *file stream object* is an object that is associated with a specific file and provides a way for the program to work with that file.

#### File Stream Objects:

- ofstream: we use this object when we want to create a file and write to it
- ifstream: we use this object when we want to open an existing file and read from it
- fstream: we use this object when we want to either read or write to a file

# 13.4 Creating a file object and opening a file

Before data can be written to or read from a file, the following things must happen:

- A file stream object must be created
- The file must be opened and linked to the file stream object

The following example shows how to open a file for input (reading):

```
std::ifstream inputfile;
inputfile.open("filename.txt");

// Or just
std::ifstream inputfile("filename.txt");

// To read from the file... (assuming there are 2 lines of text)

std::string line1, line2;

inputfile >> line1;
cout << line1;
inputfile >> line2;
cout << line2;</pre>
```

The following example shows how to open a file for output (writing):

```
std::ofstream outputfile;
   outputfile.open("filename.txt");
   // Or just
   std::ofstream outputfile("filename.txt");
   // To write to the file...
   outputfile << "Some text \n";</pre>
   // This...
10
   string a{" "};
11
   std::ofstream file("./myfile2");
12
   if (file) {
14
        while (cin \gg a && a!="q") {
15
            file << a << endl;
16
        }
17
18
   }
   file.close();
```

# 13.5 Closing a file

To close a file we write:

fileobject.close()

# 13.6 Reading from a file with an unknown number of lines

We we use the » operator to read from a file, it will return either 0 1 depending on if there was any content to read. Thus, we can use a while loop to avoid any errors.

```
while (inputfile >> line){
cout << line << endl;
}</pre>
```

# 13.7 Testing for file open errors

Under certain circumstances, the open member function will not work. For example, the following code will fail if the file info.txt does not exist:

```
ifstream inputfile;
inputfile.open("info.txt");
```

To circumvent this problem, we can use a if statement to check if the file has been opened successfully:

```
ifstream inputfile("info.txt");
if (inputfile){
    statements;
}

// Or
if (inputfile.fail()) {
    cout << "failed";
}</pre>
```

# 14 rvalues and lvalues

In C++, values are categorized as either lvalues or rvalues, which play a fundamental role in understanding expressions, value categories, and reference binding in the language.

Here's a simplified explanation:

# 14.1 rvalue (right value):

1. **Temporary** rvalues often represent temporary values that don't have a specific location in memory (i.e., you can't take their address in a straightforward manner). They are typically values that you can't assign to, like a temporary result of an expression.

### 2. Examples:

- Literals: 5, true, 'a'
- Results of most expressions: x + y, std::move(x)
- 3. **Binding:** You can't bind an rvalue to a regular (lvalue) reference (T&). However, C++11 introduced rvalue references (T&&) which can bind to rvalues. This is fundamental for move semantics and perfect forwarding.

### 14.2 lvalue

1. **Location:** An Ivalue represents an object that occupies a specific, identifiable location in memory. You can think of Ivalues as "things with a name."

# 2. Examples:

- Variables: int x;
- Dereference of a pointer: \*p
- Array subscript: arr[5]
- 3. Binding: An Ivalue can be bound to an Ivalue reference (T&).

# 15 Breaking and Continuing a loop

Concept 10: The break statement causes a loop to terminate early. The continue statement causes it to stop the current iteration and jump to the next one.

# 16 Functions

Functions in c++ are pretty simple, here is an example:

```
void myfunc() {
    statements;

int main(int argc, const char *argv[]){ myfunc(); return EXIT_SUCCESS; }

void myfunc() {
    statements;

myfunc(); return EXIT_SUCCESS; }
```

Where the type before the function identifier is the value that the function shall return.

# 16.1 Function prototypes (function declarations)

Concept 11: A function prototype eliminates the need to place a function definition before all calls to the function.

Example:

```
void foobar();

void foobar() {
    statements;

int main(int argc, const char *argv[]){ foobar(); return EXIT_SUCCESS; }

void foobar() {
    statements;

foobar(); return EXIT_SUCCESS; }
```

### 8 Note:

Function definitions can be placed below main, just prototype them above main

And we can add some parameters:

```
std::string foobar(std::string name) {
    return "Hello" + name;
}

int main(int argc, const char *argv[]){ cout << foobar("nate") << endl; } // Hello
    nate</pre>
```

### 16.2 Static locals

Sometimes we don't want a local variable to be destroyed after the function call completes, in this case we can use the static keyword before the type in our variable declarations

```
int foobar() { static int num; return num++; }

int main(int argc, const char *argv[]) {
   std::cout << foobar() << std::endl; // 0
   std::cout << foobar() << std::endl; // 1
   std::cout << foobar() << std::endl; // 2

return EXIT_SUCCESS;
}</pre>
```

We can also do default values, but these are trivial.

# 16.3 PREREQ - Reference variables

Concept 12: A reference variable in C++ is an alias, or an alternative name, for an already existing variable. Once a reference is initialized to a variable, either the variable name or the reference name can be used to refer to the variable. Reference variables must be initialized, they cannot just be declared.

```
int a = 12;
int &b = a;

description cout << a << " " << b << endl; // 12 12

a = 15;
cout << a << " " << b << endl; // 15 15

b = 20;
cout << a << " " << b << endl; // 20 20

cout << a << " " << b << endl; // 20 20</pre>
```

# 16.4 Using reference variables as parameters

**Concept 13:** When used as parameters, reference variables allow a function to access the parameters original arguments. Changes to the parameter are also made to the arguments.

Example:

```
int foobar(int &refvar) { refvar *= 2; return refvar; }
int main(int argc, const char *argv[]) {
  int num = 5;
  cout << foobar(num) << endl; // 10
  cout << foobar(num) << endl; // 20
  return EXIT_SUCCESS;
}</pre>
```

# **8** Note:

You cannot pass lvalues to a function that takes a reference variable.

# 16.5 Overloading Functions

Concept 14: Two or more functions can have the same name, as long as their parameters are different.

Example:

```
int foobar(int x, int y) { return x + y; }

int foobar(int x, int y, int z) { return x + y + z; }

int main(int argc, const char *argv[]) {

cout << foobar(1,2) << endl;
cout << foobar(1,2,3) << endl;

return EXIT_SUCCESS;
}
</pre>
```

# 16.6 The exit() function

# Concept 15:

The exit() function causes a program to terminate, regardless of which function or control mechanism is executing.

```
the exit() function is defined in the cstdlib header
```

The exit() function must be passed a integer value, usually 0 (EXIT\_SUCCESS), or 1 (EXIT\_FAILURE). We can also just pass the constants EXIT\_SUCCESS/EXIT\_FAILURE, (these constants are defined within cstdlib) Example:

```
1  exit(0);
2  exit(EXIT_SUCCESS);
3
4  exit(1);
5  exit(EXIT_FAILURE)
```

# 16.7 Stubs and Drivers

**Concept 16:** A **stub** is a *dummy* function that is called instead of the actual function it represents. It usually displays a test message acknowledging that it was called, and nothing more.

Example:

This allows for debugging by making sure the function was called at the correct time and with the correct arguments.

**Concept 17:** A **driver** is a program that tests a function by simply calling it. If the function accepts arguments, the driver passes test data.

# 17 Arrays and Vectors

# 17.1 Arrays

Concept 18: An array allows you to store and work with multiple values of the same data type. An arrays size declaration must be a constant integer expression with a value greater than or equal to zero. The amount of memory that the array uses depends on the array's data type and the number of elements.

Example:

```
int arr[3]; // array of 3 integer elements
double arr[6]; // array of 6 double elements
int myarr[3] = {1,2,3};

// Getting the elements of an array
std::cout << myarr[0]; // Outputs first value (1)</pre>
```

### **8** Note:

Arrays are defined with braces

# 17.2 Partial array initialization

We can also only initialize part of an array. In the case of an integer array, the elements that we do not define will be set to zero. Other cases depend on the data type used.

```
int arr[5] = {1,2,3}; // {1,2,3,0,0}
```

# 17.3 Implicit array sizing

Its possible to define an array without specifying a size, as long as we provide an initialization list, c++ will automatically make the array large enough to hold all of the initialization values.

# 17.4 Bound violation

If we try to add values to a function without any remaining space, the program will crash.

# 17.5 The range based for loop

Concept 19: The range-base for loop is a loop that iterates once for each element in an array.

Example:

```
int lastindex;
lastindex = (sizeof(arr) / sizeof(arr[0])-1);
for (int i: arr) {
    if (i != arr[lastindex]) {
        cout << i << ",";
    } else {
        cout << i;
}
</pre>
```

# 17.6 Modifying an array with a range-based for loop

We can declare the range variable as a reference. This way, any change made to i will be reflected in our array.

```
int arr[3] = {1,2,3};

for (int &i: arr) {
    i = 5;
  }

for (int i : arr) cout << i << " "; // 5 5 5</pre>
```

### 17.7 Thou shall not assign

It is crucial to understand that we can not simply assign an array to some other array variable. The only way to copy over the array to a new variable is to use a loop. Whenever we refer to an array by just its identifier, we are only referring to its beginning memory address.

A corollary to this concept would lead to the conclusion that we will also not be able to print the contents of an array by:

```
int arr[5] = {1,2,3,4,5};
std::cout << arr << std::endl;
</pre>
```

This will only display the arrays **memory address**, we must use a loop to display the contents.

# 17.8 Getting the size of an array

To get the size of the array, we can use the sizeof() function. The way this works is we get the size of the entire array, and then divide by the size of any element.

```
int arr[3] = {1,2,3};
std::cout << sizeof(arr) / sizeof(arr[0]) << std::endl; // 3

// We can also get the last index position by subtracting one
std::cout << sizeof(arr) / sizeof(arr[0]) - 1 << std::endl; // 3</pre>
```

# 17.9 Arrays as function arguments

Concept 20: To pass an array as an argument to a function, pass the name of the array. When we pass an array to a function, we are passing a reference to the array, this means any changes to the array in the function will be reflected to the array we passed.

```
int main(int argc, const char *argv[]) {
        const int SIZE = 3;
        int myarr[3] = \{1,2,3\};
        for (int i: myarr) cout << i << endl; // 1 2 3</pre>
6
        foobar(myarr, SIZE);
        for (int i: myarr) cout << i << endl; // 2 3 4
10
11
12
13
        return EXIT_SUCCESS;
14
15
   }
16
    void foobar(int arr[], int size) {
17
18
        for ( int i=0; i < size; ++i ) {</pre>
19
             arr[i]++;
20
        }
21
22
23
   }
24
```

## 8 Note:

If we do not wish for a function to make any changes to the array argument, we must declare it as const in the function parameters.

# 17.10 2D array (matrix)

Concept 21: A two-dimensional array is like sereval identical arrays put together. It is useful for storing multiple sets of data. In mathematics, this type of concept would be called a matrix

Consider the arrays:

Then we have:

$$A = \{a_1, a_2, a_3\}$$

$$a_1 = \{1, 2, 3\}$$

$$a_2 = \{4, 5, 6\}$$

$$a_3 = \{7, 8, 9\}$$

$$\begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 9 \end{bmatrix}.$$

So in C++, this would be:

The way we can output all elements of this matrix would look something like:

```
const int SIZE = 3;
    int arr[3][3] = {
                  \{1,2,3\},
                  \{4,5,6\},
                  {7,8,9}
             };
    for (int i{0}; i < SIZE; ++i) {</pre>
         for (int j{0}; j < SIZE; ++j)</pre>
10
         {
              cout << arr[i][j] << " ";
11
         }
12
         cout << endl;</pre>
13
    }
14
```

```
const int ROW_SIZE = 3;
    const int COLUMN_SIZE = 4;
    int arr[ROW_SIZE] [COLUMN_SIZE] = {
                  \{1,2,3\},
                  \{4,5,6,6\},
                  {7,8,9}
             };
    for (int i{0}; i < ROW_SIZE; ++i)</pre>
         for (int j{0}; j <</pre>
10
        COLUMN_SIZE; ++j) {
             cout << arr[i][j] << " ";
11
12
         cout << endl;</pre>
13
    }
14
```

# 17.11 Passing a matrix to a function

Unlike array parameter declarations not needing a size, matrix parameters do.

```
const int ROW_SIZE = 3;
    const int COLUMN_SIZE = 4;
    void foobar(const int arr[][COLUMN_SIZE], int row_size) {
        for (int i{0}; i < row_size; ++i) {</pre>
             for (int j{0}; j < COLUMN_SIZE; ++j) {</pre>
                 cout << arr[i][j] << " ";</pre>
             }
             cout << endl;</pre>
        }
10
    }
11
12
    int main(int argc, const char *argv[]) {
13
14
        int arr[ROW_SIZE] [COLUMN_SIZE] = {
16
                      \{1,2,3\},
                      {4,5,6,6},
                      {7,8,9}
                 };
20
        foobar(arr, ROW_SIZE);
22
        return EXIT_SUCCESS;
24
   }
25
```

### 17.12 The STL Vector

**Concept.** The *Standard Template Library* offers a **vector** data type, which in many ways, is superior to standard arrays.

The STL is a collection of data types and algorithms that you may use in your programs.

A **vector** is a container that can store data. It is like an array in the following ways:

- A vector holds a sequence of values.
- A vector stores its elements in a contiguous memory location.
- You can use the array subscript operator []

## 17.13 Defining a vector

```
#include <vector>
std::vector<type> name(size); // size is optional
// Examples
std::vector<int> a(3); // Vector of ints, size 3 with fill of zeros
std::vector<int> a(3, 2); // Vector of ints, size 3 with fill of twos
std::vector<int> a(othervector) // Copy of some other vector
std::vector<int> b = {1,2,3}; // Vector of ints
std::vector<int> b {1,2,3}; // Vector of ints
std::vector<int> b {1,2,3}; // Vector of ints
```

### **8** Note:

If we declare a size for the vector, we **cannot** define its elements in the same statement, defining elements of a vector in the same statement in which it's declared automatically defines its size, so manually doing is not only not needed, but will produce an error.

### 17.14 Get index position of elements

To get the index position of an element in a vector, we can use the at(pos) member function.

Example:

```
std::vector<int> a {1,2,3};
cout << a.at(0); // 1</pre>
```

# 17.15 Adding to a vector

To store a value in a vector that does not have a starting size, or that is already full, use the **push\_back()** member function. This function accepts an element and stores it at the end of the vector.

```
std::vector<int> a {1,2,3};
a.push_back(4);
```

# 17.16 Getting the size of a vector

To get the size of a vector, we can use the size() member function.

Example:

```
std::vector<int> a {1,2,3};
std::cout << size(a) << std::endl; // 3</pre>
```

# 17.17 Removing last element of a vector

To remove elements from a vector, we can utilize the **pop\_back()** member function. This function will remove the last element of the vector.

Example:

```
std::vector<int> a {1,2,3};
a.pop_back(); // Removes the last element (3).
```

# 17.18 Removing elements of a vector

To remove elements:

```
std::vector<int> myvec{1,2,3,4};
myvec.erase(myvec.begin() + 1); // Removes the second element (2)
```

# 17.19 Clearing a vector

To clear a vector we can use the **clear()** member function.

Example:

```
std::vector<int> a {1,2,3};
a.clear();
```

# 17.20 Detecting an Empty vector

To determine if a vector is empty, we can use the **empty()** function. This function will return 0 or 1 depending on whether the vector contains any elements.

```
std::vector<int> a {1,2,3};
std::vector<int> b;
cout << a.empty(); // 0
cout << b.empty(); // 1</pre>
```

# 17.21 Resizing a vector

To resize a vector, we can use the **resize()** member function.

Example:

```
std::vector<int> a {1,2,3};
a.resize(5,2); // resize the vector to a total size of 5 elements, filling with 2s.
a.resize(5); // resize the vector to a total size of 5 elements, filling with 0s.
```

# 17.22 Swapping Vectors

To swap the contents of two vectors, we can use the swap(vector) member function.

```
std::vector<int> v1 {1,2,3};
std::vector<int> v2 {4,5,6};

v1.swap(v2);
```

# 18 Searching and Sorting Arrays

**Concept 22:** A search algorithm is a method of locating a specific item in a larger collection of data. This section discusses two algorithms for searching the contents of an array.

### 18.1 The linear search

The linear search is very simple, it uses a loop to sequentially step through an array, starting with the first element.

```
int main(int argc, const char *argv[]) {
        const int SIZE = 5;
        int arr[SIZE] = {88,67,5,23,19};
        int target = 5;
        for (int i{0}; i <= SIZE + 1; ++i) {
            if (i == SIZE + 1) {
                cout << "Target not in array" << endl;</pre>
10
11
            if ( arr[i] == target ) {
12
                cout << "Target [" << target << "] found at index position " << i <<</pre>
        endl;
                break;
            }
15
        return EXIT_SUCCESS;
17
   }
```

```
int linearsearch(int arr[], int size, int target) {
        int index{0}, position{-1};
2
        bool found = false;
        while (index < size && !found) {
            if (arr[index] == target) {
                position = index;
                found = true;
            }
            ++index;
10
        }
       return position;
12
   }
13
```

One drawback to the linear search is its potential inefficiency, its quite obvious to notice that for large arrays, the linear search will take a long time, if an array has 20,000 elements, and the target is at the end, then the search will have to compare 20,000 elements.

# 18.2 The binary search

The binary search algorithm is a clever approach to searching arrays. Instead of testing the array's first element, the algorithm starts with the leement in the middle. If that element happens to contain the desired value, then the search is over. Otherwise, the value in the middle element is either greater than or less than the value being searched for. If it is greater, then the desired value (if it is in the array), will be found somewhere in the first half of the array. If it is less, then the desired value, it will be found somewhere in the last half of the array. In either case, half of the array's elements have been eliminated from further searching.

# Note:

The binary search algorithm requires the array to be sorted.

Example:

```
int binarysearch(int arr[], int size, int target) {
        int first{0},
2
            middle,
            last = size -1,
            position{-1};
        bool found = false;
        while (!found && first <= last) {</pre>
            middle = (first + last) / 2;
10
            if (arr[middle] == target) {
11
                found = true;
                position = middle;
13
            } else if (target > arr[middle]) {
                 first = middle + 1;
15
            } else {
16
                 last = middle - 1;
17
            }
        }
19
        return position;
20
   }
21
```

Powers of twos are used to calculate the max number of comparisons the binary search will make on an array. Simply find the smallest power of 2 that is greater than or equal to the number of elements in the array. For example:

```
n = 50,000
2^{15} = 32,768
2^{16} = 65,536.
```

Thus, there are a maximum of 16 comparisons for a array of size  $50,\!000$ 

### 18.3 Bubble Sort

The bubble sort algorithm makes passes through and compares the elements of the array, certain values "bubble" toward the end of the array with each pass.

Example:

```
void swap(int &a, int &b) {
        int temp = a;
2
        a = b;
3
        b = temp;
   void bubblesort(int arr[], int size) {
        for (int max = size; max > 0; --max) {
9
            for (int i{0}; i < size; ++i) {</pre>
                 if (arr[i] > arr[i + 1]) {
11
                     swap(arr[i], arr[i+1]);
12
                 }
13
            }
14
        }
15
   }
16
```

### 18.4 Selection Sort

The bubble sort algorithm is simple, but it is ineffective because values move by only one element at a time toward their final destination in the array. The *selection sort algorithm* usually performs fewer swaps because it moves items immediately to their final position in the array.

```
void swap(int &a, int &b) {
        int temp = a;
2
        a = b;
        b = temp;
   }
   void selectionsort(int arr[], int size) {
        for(int j=0; j < size; ++j) {
10
            int &minelement = arr[j];
11
            for (int k = j+1; k < size; ++k) {
                 if ( arr[k] < minelement ) {</pre>
13
                     swap(minelement, arr[k]);
15
            }
16
17
        }
18
   }
19
```

The selection sort starts with the assumption that the first element is already the smallest, then it scans the array and tries to find a smaller value. If one is found, it moves that element to the front. Once the iteration is complete, we can be sure that the smallest value is at the front and +1 is added to the loop index.

# 19 Pointers

Concept 23: Pointers are variables that store the memory address of a variable, we can use the & operator to retrieve the address of a variable. Pointers are like references, any changes we make to the variable the holds the pointer, the change will be reflected in the original variable.

# **8** Note:

In order to access the contents of a pointer, we must dereference, more on this later.

Example:

```
int a = 12;
int *b; // Initialize pointer
b = &a; // Get the memory address of a and store in b
cout << b; // Output the memory address
cout << *b; // Output the contents
*b = 15; // Change the value of b, change reflected to a
// We can also put the asterisk next to the type
int* b;</pre>
```

# 19.1 Nullptr

It is never a good idea to use an uninitialized pointer, this could mean we are affecting some random memory address. To circumvent this, we can use the bulitin keyword *nullptr*. Assigning a pointer to nullptr means we are assigning it to the address zero. When we do this, we say that the pointer points to "nothing".

```
int* b = nullptr;
```

# **8** Note:

If we try to deference the contents of a nullptr, we will get address boundary error at runtime

# 19.2 Arrays as pointers

Concept 24: Array names can be used as constant pointers, and pointers can be used as array names.

We have already discussed that referencing an array without the subscript operator returns the address of the beginning of the array. Thus, we can conclude that an array is just a *pointer* to the first element.

If we deference an array, we can get access to the first element.

```
int arr[3] = {1,2,3};
cout << *arr << endl; // 1</pre>
```

We can gain access to the other elements via some simply arithmetic:

```
int arr[3] = {1,4,3};
cout << *(arr+1); // 4</pre>
```

We we add one to *arr*, we are actually adding 1 multiplied by the size of the data type that we are trying to access. This allows us to change the address of the first element to the address of the second.

Therefore, we can generalize:

```
1 arr[index] = *(arr + index)
```

We can assign pointers to arrays

```
int arr[3] = {1,2,3};
int* b = arr;
cout << *b << endl; // 1
for (int i{0}; i < 3; ++i) {
    cout << b[i] << endl;
}</pre>
```

### 19.3 Pointers as Function Parameters

We can also declare pointer parameters in functions, giving the function access to the original variable, much like reference

```
void foobar(int* pt) {
    *pt = 5;
}

int a = 10;
foobar(&a); // Changes a to the value 5
```

### 19.4 Pointers to constants

Sometimes, it is necessary to pass the address of a const item into a pointer. When this is the case, the pointer must be defined as a pointer to a const item.

```
const int* b;
const int *b;
```

### 8 Note:

It should be noted that the keyword const is referring to the thing that b is pointing to, not b itself. Furthermore, it is crucial that we have the const modifier on line 2, if we are trying to point to a constant, then this is required. This does not mean the thing we are trying to point to needs the const qualifier for line 2 to be valid. lastly, because b is a pointer to a const, the compiler will not allow us to write code that changes the thing that b points to.

### 19.5 Constant Pointers

We can also use the const key word to define a constant pointer. Here are the differences:

- A pointer to a const points to a constant item. The data that the pointer points to cannot change, but the pointer itself can change.
- With a const pointer, it is the pointer itself that is constant. Once the pointer is initialized with an address, it cannot point to anything else.

Example:

```
int* const ptr;
int *const ptr;
```

## 19.6 Both pointer to constant and constant pointer

```
const int* const ptr;
const int *const ptr;
```

# 19.7 Prereq - Static vs Dynmaic memory allocation

There are different types of memory allocation in a C++ program. By default, creating variables will utilize "static memory allocation", this is where variables are created on the "stack". The stack is a region of memory where local variables, function parameters, return addresses, and control flow data are stored. It operates in a Last-In-First-Out (LIFO) manner.

When a function is called, a new "stack frame" is pushed onto the stack. This frame contains the function's local variables, parameters, and the return address. When the function returns, its stack frame is popped off, and the stack pointer moves back to the previous frame. The stack grows and shrinks automatically as functions are called and return.

#### Characteristics:

- Automatic Memory Management: Memory allocation and deallocation on the stack are automatic. When a function exits, its local variables are automatically deallocated.
- Speed: Stack operations (push and pop) are very fast.
- **Fixed Size:** The stack has a fixed size, determined at the start of the program. If a program uses more stack space than is available (e.g., due to deep or infinite recursion), it will result in a "stack overflow."

In constrast to this, we also have **dynmaic memory allocation**: In has the following characteristics:

- Memory is allocated during runtime.
- Uses functions like malloc(), calloc(), realloc(), and new (in C++) to allocate memory.
- Requires manual deallocation using functions like free() or delete (in C++).
- Memory is allocated on the heap.
- The size of the memory allocation can be determined at runtime based on program needs.

## 19.8 Dynamic Memory Allocation

Concept 25: Variables may be created and destroyed while a program is running.

In the cases where we don't know how many variables we will need for a program, we can allow a program to create its own variables "on the fly". This is called *dynamic memory allocation* and this is only possible through pointers.

To dynamically allocate memory means that a program, while running, asks the computer to set aside a chunk of unused memory large enough to hold a variable of a specific data type. Let's say a program needs to create an integer variable. It will make a request to the computer that it allocate enough bytes to store an int. When the computer fills this request, it finds and sets aside a chunk of unused memory large enough for the variable. It then gives the program the starting address of the chunk of memory. The program can only access the newly allocated memory through its address, so a pointer is required to use those bytes.

The way a C++ program requests dynamically allocated memory is through the new operator. Assume a program has a pointer to an int defined as

```
int *ptr = nullptr;
// Then we can do:
ptr = new int;
// A value may be stored in this new variable by dereferencing the pointer:
*ptr = 15;
```

This statement is requesting that the computer allocate enough memory for a new int variable. The operand of the new operator is the data type of the variable being created. Once the statement executes, ptr will contain the address of the newly allocated memory. Then we store a value in the new variable by dereferencing.

Although the statements above illustrate the use of the new operator, there's little purpose in dynamically allocating a single variable. A more practical use of the new operator is to dynamically create an array. Here is an example of how a 100-element array of integers may be allocated:

```
1 ptr = new int[100];
```

Once the array is created, the pointer may be used with subscript notation to access it.

it should release it for future use. The delete operator is used to free memory that was allocated with new. Here is an example of how delete is used to free a single variable, pointed to by iptr:

```
delete ptr;
ptr = nullptr; // Always set to nullptr after deleting
delete [] ptr; // If ptr points to a dynamically allocated array
ptr = nullptr; // Always set to nullptr after deleting
```

### **8** Note:

Failure to release dynamically allocated memory can cause a program to have a memory leak. Only use pointers with delete that were previously used with new. If you use a pointer with delete that does not reference dynamically allocated memory, unexpected problems could result!

### 19.9 When to use DMA

- 1. Memory Location: The integer is allocated on the heap.
- 2. Lifetime: The memory remains allocated until it's explicitly deallocated using delete.
- 3. Use Cases:
  - Variable Size: When you need data structures of variable size, like linked lists or dynamic arrays.
  - Long-lived Objects: When you need objects that outlive the function they were created in.
  - Avoiding Stack Overflow: For large allocations, the stack might not have enough space, leading to stack overflow. In such cases, DMA is preferred.
  - For Polymorphism: In object-oriented programming, DMA is often used with pointers to base and derived classes to achieve polymorphism.

## 19.10 Returning pointers from a function

Concept 26: Functions can return pointers, but you must be sure the item the pointer references still exists.

We should return a pointer from a function only if it is:

- A pointer to an item that was passed into the function as an argument.
- A pointer to a dynamically allocated chuck of memory

### 19.11 Smart Pointers

Concept 27: C++ 11 introduces smart pointers, objects that work like pointers, but have the ability to automatically delete dynamically allocated memory that is no longer being used.

We have three types:

- unique\_ptr: The sole owner of a piece of dynamically allocated memory.
- **shared\_ptr**: Can share ownership of a piece of dynamically allocated memory. Multiple pointers of the shared\_ptr type can point to the same piece of memory
- weak\_ptr: Does not own the memory it points to, and cannot be used to access the memory's contents. Used when the memory pointed to by a shared\_ptr must be referenced without increasing the number of shared\_ptrs that own it.

#### Note:

To use these smart pointers, we must include <memory>

Here is the syntax for a unique pointer:

```
unique_ptr<type> name( new type );
// Example
std::unique_ptr<int> a( new int ); // Basic way
std::unique_ptr<int> a = std::make_unique<int>(15); // Preferred Way
(Initialization of 15)
std::unique_ptr<int> a = std::make_unique<int>(); // Preferred Way (initialization of zero)
std::shared_ptr<int> b = a; // NOT VALID, unique_ptr must be unique
```

So now we have two entities: a **unique\_ptr** located on the *stack* and an **int** located on the *heap*. The unique\_ptr holds the address of the int we created on the heap. Since this is a **smart pointer**, the integer object will be deleted and the unique pointer that was holding the memory address will be set to nullptr will be deleted and the unique pointer that was holding the memory address will be set to **nullptr**.

A shared\_ptr works via a reference counter maintained in a control block. This mechanism keeps track of how many shared\_ptr instances are pointing to the same object. Once the reference count reaches zero, the managed object is deleted. The control block also tracks weak references and is deallocated when both shared and weak counts reach zero. Here is how we build such object:

Lastly, we can define a **weak\_ptr**, we can assign this object to any shared\_ptr object, but the reference count will not be updated.

```
std::shared_ptr<int> a = std::make_shared<int>(10);
std::weak_ptr<int> b = a; // Reference count will NOT be updated.
```

# 20 Characters, C-Strings and more about the string class

# 20.1 Character Testing

The C++ library provides several functions that allaw us to test the value of a character. These functions test a single *char* argument and return either true or false.

To use these functions, we must include <cctype>

- isalppha
- isalnum
- isdigit
- islower
- isprint
- ispunct
- isupper
- isspace

### 20.2 Character case conversion

We also have functions for converting characters to uppercase or lowercase.

- toupper
- tolower

# 20.3 C Strings

**Concept 28:** A C-string is a sequence of characters stored in consecutive memory locations, terminated by a null character. In C++, all string literals are stored in memory as C-Strings. The purpose of a **null terminator** is to mark the end of the C-String.

It's important to realize that a string literal has its own storage location, just like a variable or an array. When a string literal appears in a statement, it's actually its memory address that C++ uses.

## 20.4 C-Strings stored in arrays

In C, there is no string class that we can use, so when a C programmer wants to create a string, they must make a char array to house it. The char array must be large enough to house the string, and one extra to hold the null terminator.

Here's how we get input from a user and store it in a character array (string)...

```
const int SIZE=80;
char a[];
cout << "enter some string: ";
cin.getline(a,SIZE);</pre>
```

Here we are using the cin's member function **getline()**, where the first argument is where we want to store the input, and the second argument indicates the maximum length of the string, including the null terminator

For a summary:

```
std::getline(cin, variable) // Used for std::string objects
cin.get(variable) // Used for single characters
cin.getline(variable, size) // Used for character arrays
```

### **8** Note:

We cannot use const char\* for user input

### 20.5 The Strlen function

To be able to get access to various function pertaining to C-Strings, we must include <cstring>. Then we can get the size of a string by:

```
char name[] = "NATE";
int len;
len = strlen(name);
// These functions are also going to work for the other type of C-String
const char* a;
len = strlen(a);
```

### **8** Note:

The strlen function accepts a pointer to a C-String. Also know that sizeof() will include the null terminator, while strlen will not

# 20.6 The streat Function

The streat function accepts two pointers to C-Strings as its arguments. The function then concatenates, or appends one string to another.

```
char a[20] = "Hello ";
char b[] = "World";
strcat(a,b);

cout << a << endl; // Hello World!

char a[20] = "Hello ";
const char* b = "World";
strcat(a,b);

cout << a << endl; // Hello World!</pre>
```

# **8** Note:

With the second example, a cannot be a const char\*, and they cannot both be const char\*

# 20.7 The Streepy function

Recall that one array cannot be assigned to another array with the = operator. The strepy function can be used to copy one string to another.

```
char a[10];
char b[] = "Hello";
strcpy(a,b);
cout << a << endl; // Hello
// We can also do...
char a[10];
const char* b = "Hello";
strcpy(a,b);
cout << a << endl; // Hello</pre>
```

### **8** Note:

For the second example, the thing we are copying to cannot be a const char\*

# 20.8 The strncat and strncpy functions

Because the **strcat** and **strcpy** functions can possibly overwrite the bounds of an array, they make it possible to write unsafe code. Instead, you should use **strncat** and **strncpy** when possible

**Remark.** "Overwriting the bounds of an array" refers to accessing or modifying elements of an array outside of its valid index range. In simpler terms, it means trying to read from or write to a location that's not within the array's allocated memory.

These functions have an additional parameter, it is the maximum number of characters to add to the array. This way, we can define how much space we have left for the string, and pass it to these functions to make sure we don't go out of bounds.

```
// strncat
   const int SIZE=10;
   char a[SIZE] = "Hello, ";
   const char* b = "World";
   int size_left = SIZE - strlen(a);
   strncat(a,b,size_left); // Hello, Wor
   // strncpy
   const int SIZE=3;
   char a[SIZE];
11
   const char* b = "World";
12
13
   strncpy(a,b,SIZE);
15
   cout << a << endl; // Wor</pre>
```

### 20.9 The strstr function

This function searches for a string inside of a string. For instance, it could be used to search for the string "seven" inside the larger string.

```
const char* a = "hello world";
const char*b = nullptr;
b = strstr(a, "hello")

cout << b << endl; // hello world</pre>
```

### Note:

If the substr is found, it will return the substr and all that comes after it

# 20.10 The strcmp function

This function takes two C-Strings as arguments and returns an integer that indicates how the two strings compare to each other.

- The result is zero if the two strings are equal on a character-by-character basis.
- The result is negative if string1 comes before string2 in alphabetical order.
- The result is positive if string1 comes after string2 in alphabetical order.

```
const char* a = "Nate";
const char* b = "Warner";

if (!strcmp(a,b)) {
    cout << "These strings are the same" << endl;
} else if (strcmp(a,b) < 0) {
    cout << a << "comes before " << b << "in alphabetical order" << endl;
} else {
    cout << a << "comes after " << b << "in alphabetical order" << endl;
}
</pre>
```

# 20.11 String/Numeric Conversion Functions

**Concept 29:** The C++ library provides functions for converting C-Strings and string objects to numeric data types and vice versa.

#### String to number (C-String)

- atoi: converts C-String to an integer
- atol: converts C-String to a long integer
- atof: converts C-String to a double

•

### String to number (C++ String)

```
• stoi: int
```

• stol: long

• stoul: unsigned long

• stoll: long long

• stoull: unsigned long long

• **stof**: float

• stod: double

• stold: long double

# Number to String (Returns string object)

• to\_string

### 20.12 More on the C++ string (string object)

Unlike C-Strings, there is no need to use a function like strcmp to compare two strings, we can just use the comparison operators. Much like any scripting language you may be familiar with. Not going to go over this stuff, its pretty trivial.

### 20.13 C++ String definitions

We have various ways to declare and define these string objects.

```
string a; // Defines empty string
string a("text"); // Directly call constructor
string a(otherstring) // Copy
string a(otherstring, 5) // Copy, only use the first 5 characters
string a(otherstring,1,5) // Copy, only use characters 1-5
string a('z', 10) // 10 z characters
```

### 20.14 C++ string supported operators

- »
- "
- =
- +=
- +

(subscript notation)

### 21 Structures

Concept 30: Abstract data types (ADTs) are data types created by the programmer. ADTs have their own range (or domain) of data and their own sets of operations that may be performed on them. In C++, we can make use of the concept of **structures** to create these abstract types.

#### 21.1 Abstraction

An abstraction is a general model of something. It is a definition that includes only the general characteristics of an object.

### 21.2 Abstract data types

An ADT is a data type created by the programmer and is composed of one or more primitive data types. The programmer decides what values are acceptable for the data type, as well as what operations may be performed on the data type. In many cases, the programmer designs his or her own specialized operations.

#### 21.3 Structures

Concept 31: C++ allows us to group several variables together into a single item known as a structure

The syntax for a structure is as follows:

```
struct tag {
variable declarations;

// ... More declarations
// may follow...
};
```

Suppose we had a payroll system where we have a bunch of variables that are related to each other, then we could define a structure...

```
struct Payroll {
    // Members
    int empNumber;
    string name;
    double hours;
    double payrate;
    double grossPay;
    };
```

### **8** Note:

Notice the semi colon at the end of the structure definition

It's important to be aware that the structure example in our example does not define a variable. It simply tells the compiler what a payroll structure is made of.

Now that we have our structure defined, we can define variables of this type with simple definition statements.

```
payroll deptHead;
```

### 21.4 Accessing structure members

Concept 32: The dot operator allows us to access structure members in a program.

```
deptHead.empNumber = 475;
```

### 21.5 Initializing a structure (Initialization list)

Concept 33: The members of a structure variable may be initialized with starting values when the structure variable is defined

Consider the example found in the above subsections (Payroll). We can then define a Payroll variable with an initialization list...

#### 21.6 Arrays of structures

Concept 34: Arrays of structures can simplify some programming tasks

Example:

```
struct BookInfo {
string title;
string author;
string publisher;
double price;
};
const int SIZE = 20;
BookInfo bookList[SIZE];
```

Here we defined an array, bookList, that has 20 elements. Each element is a BookInfo structure.

So we can step through the array to get the contents:

```
for (int i=0; i<SIZE; ++i) {
    cout << bookList[i].title << endl;
    cout << bookList[i].author << endl;
    cout << bookList[i].publisher << endl;
    cout << bookList[i].price << endl;
}</pre>
```

#### 21.7 Initializing a structure array

To initialize a structure array, we can simply use a initialize list, still considering the above structure example, we can do:

#### 21.8 Nested Structures

Its possible for a structure variable to be a member of another stricter variable.

```
struct foo {
   int a;
   int b;
};
struct bar {
   int c;
   foo f1;
};
bar b1;
cout << b1.f1.a;</pre>
```

### 21.9 Structures as function arguments

Concept 35: Structure variables may be passed as arguments to functions

```
struct Box {
    double 1, w;
    double 1, w;
    void Showbox(Box box) {
        cout << box.1 << endl << box.w;
    }
}</pre>
```

#### **8** Note:

This is a pretty poor example, but it shows the concept

#### 21.10 Constant reference parameters

**Concept 36:** Sometimes structures can be quite large. Passing large structures by value can decrease a program's performance. Of course, this can be dangerous, as passing by reference means we can alter the original values. However, we can circumvent this by passing the argument as a constant reference.

```
struct Box {
   double 1, w;
};

void Showbox(const Box& box) {
   cout << box.l << endl << box.w;
}
</pre>
```

### 21.11 Returning a structure from a function

Concept 37: A function may return a structure

```
struct Circle {
       double radius;
       double diameter;
       double area;
   Circle getCircleData() {
       Circle temp;
10
       temp.radius = 10.0;
       temp.diameter = 20.0;
11
       temp.area = 314.159;
12
       return temp;
13
   }
14
   myCircle = getCircleData();
```

#### 21.12 Pointers to structures

Concept 38: You may take the address of a structure variable and create variables that are pointers to structures

```
circle myCircle{10.0,20.0,314.159};
circle* cirptr = nullptr;
cirptr = &mycircle;
// Access
**cirptr.radius = 10; // Doesn't work
(*cirptr).radius = 10; // Works
cirptr->radius = 10; // Special syntax
```

#### 21.13 Dynamically allocating a structure

We can also use a structure pointer and the new operator to dynamically allocate a structure

```
1 Circle *cirptr = nullptr;
2 cirptr = ( new Circle );
3 cirptr->radius = 10;
4 delete cirptr; // Don't forget to delete when your done with it.
```

#### **8** Note:

We use the arrow operator to access *pointers to structure objects*, not structures who's members are pointers. To access structure pointer members, we use the syntax in the above syntax labeled "Doesn't work

Lastly, in the case we have a pointer to a structure that contains a pointer member, we need to use a mix of the deference operator **and** the arrow operator.

```
1 *ptr->member;
2 // or
3 *(*ptr).member;
```

#### 21.14 Enumerated data types

**Concept 39:** An **enumerated** data type is a programmer defined data type. It consists of values known as **enumerators**, which represent integer constants

```
enum Day { MONDAY, TUESDAY, WEDNESDAY, THURSDAY, FRIDAY};
   cout << MONDAY << endl</pre>
2
        << TUESDAY << endl
        << WEDNESDAY << endl
        << THURSDAY << endl
        << FRIDAY;
   /*
   0
   1
   2
10
   3
   4
12
13
   */
   Day d1; //
                      We can also create variables of the data type
```

Because d1 is a variable of the Day data type, we may assign any of the enumerators MONDAY, TUESDAY, WEDNESDAY, THURSDAY, or, FRIDAY to it.

We can think of these enumerators as integer named constants.

#### 21.15 Assigning an integer to an enum variable

We cannot directly assign integer values to enum variables. For example, the following code will produce an error.

```
enum Day { MONDAY, TUESDAY, WEDNESDAY, THURSDAY, FRIDAY};
Day d1;
d1 = 10; // Error
```

Instead, we must cast the integer literal to data of type **Day**.

```
1 d1 = static_cast<Day>(10); // Works
```

#### 21.16 Assigning an enumerator to an int variable

We cannot directly assign an integer value to an enum variable. We can, however, directly assign an enumerator to an integer variable.

```
int x{0};
   x=MONDAY; // Works just fine
```

We can also assign a variable of an enumerated type to an integer variable

```
Day d1 = MONDAY;
int x = d1;
```

When we don't need to define any variables of the enumerated type, we can actually skip the naming process. When this occurs, we say we have an **anonymous enumerated type** 

### 21.17 Using math operators to change the value of an enum variable

Again, we must use a cast.

```
enum Day { MONDAY, TUESDAY, WEDNESDAY, THURSDAY, FRIDAY};

Day d1 = MONDAY;
d1 = d1 + 1; // Error
d1 = static_cast<Day>(d1 + 1); // Correct
```

#### 21.18 Using an enum variable to step through an array's elements

#### 21.19 Specifying values in enumerators

```
1 enum {a=1,b,c,d}; // This will start at 1 instead of 0
2 enum {a=1,b=5,c=10,d=15};
```

### 21.20 declaring the type and defining the variables in one statement

```
enum myenum {a,b,b,c} e1;
enum myenum {a,b,b,c} e1,e2;
```

### 21.21 Strongly typed enums

Normally, you cannot have multiple enumerators with the same name. However, we can define whats called a **strongly typed enum**, also known as **enum class**.

```
enum class Presidents { MCKINLEY, ROOSEVELT, TAFT };
enum class VicePresidents { ROOSEVELT, FAIRBANKS, SHERMAN };
Presidents prez = Presidents::ROOSEVELT;
Presidents vp = VicePresidents::ROOSEVELT;
```

If we want to retrieve the values, we must cast to an int.

```
cout static_cast<int>(Presidents::ROOSEVELT);
```

If we want to specify a underlying type for a strongly typed enum, we can do:

```
enum class Day : char {M,T,W,TH,F};
```

## 22 String streams

String streams in C++ are part of the stream-based I/O library and are very useful when it comes to performing input/output operations on strings. They behave similarly to input and output streams, but instead of reading from or writing to external devices like the console or a file, they operate on in-memory strings.

There are three primary string stream classes defined in the <sstream> header:

- std::istringstream: This is an input string stream. It allows you to treat a string as an input stream. You can extract values from a string much like how you would from std::cin.
- std::ostringstream: This is an output string stream. It allows you to perform output operations on a string, essentially letting you build or modify a string using stream insertion operations.
- std::stringstream: Combines the functionalities of both istringstream and ostringstream. It can be used for both input and output operations on a string.

#### 22.1 Using istringstream

Example:

#### 22.2 Using ostringstream

We can use this stream to build strings, we use *stream*.str() to access the built string

Example:

```
int age = 25;
std::string name = "Alice";
std::ostringstream oss;

oss << name << " is " << age << " years old.";

std::cout << oss.str() << std::endl; // Outputs: Alice is 25 years old.</pre>
```

# 23 Advanced file operations

```
fstream file("thing.txt", std::ios::in | std::ios::out);
```

### 24 C++ Lambdas

Concept 40: Lambdas are used to create anonymous functions.

General syntax:

```
auto name = [ capture_clause ] ( parameters ) -> return_type { body }
```

Where:

- Capture Clause: Specifies which variables from the surrounding scope are available inside the lambda, and whether they are captured by value or by reference.
- Parameters: Like regular functions, lambdas can take parameters.
- Return Type: Optional. If omitted, the compiler will infer the return type based on the return statements in the lambda.
- Body: The code to be executed when the lambda is called.

Example:

```
int x = 10;
auto add = [x](int y=0) -> int { return x+y; };
int z = add(5); // 15
```

### 24.1 Options for capturing

• Capture Nothing ([]): No variables from the enclosing scope are captured. The lambda cannot use any outside variables that are not passed as parameters.

```
1 auto lambda = []() { /* ... */ };
```

• Capture by Value ([=]): All variables used in the lambda body are captured by value. Each variable is copied into the lambda.

```
int x = 10;
auto lambda = [=]() { return x; }; // x is captured by value
```

• Capture by Reference ([&]): All variables used in the lambda body are captured by reference. The lambda operates on the original variables, not copies.

```
int x = 10;
auto lambda = [&]() { x = 20; }; // x is captured by reference
```

• Capture Specific Variable by Value ([x]): Only the specified variable (x in this case) is captured by value.

```
int x = 10, y = 20;
auto lambda = [x]() { return x; }; // Only x is captured by value
```

• Capture Specific Variable by Reference ([&x]): Only the specified variable (x in this case) is captured by reference.

```
int x = 10, y = 20;
auto lambda = [&x]() { x = 30; }; // Only x is captured by reference
```

• Capture Some by Value and Others by Reference ([x, &y]): You can mix capturing by value and by reference. In this example, x is captured by value and y by reference.

```
int x = 10, y = 20;
auto lambda = [x, &y]() { /* ... */ };
```

• Capture by Value, but Mutable ([=]() mutable ... ): By default, a lambda that captures by value is const, meaning you can't modify the captured variables. Adding mutable allows modification of the copies of the captured variables.

```
int x = 10;
auto lambda = [=]() mutable { x = 20; }; // x is a modifiable copy
```

• Capture the Current Object by Value ([\*this]): In a member function, captures the current object (\*this) by value, useful in C++17 and later.

```
struct MyClass {
int x = 10;
auto getLambda() { return [*this]() { return x; }; }
}
```

• Default Capture by Reference, Specific by Value ([&, x]): Captures most variables by reference, but x is captured by value.

```
int x = 10, y = 20;
auto lambda = [&, x]() { /* ... */ };
```

• Default Capture by Value, Specific by Reference ([=, &y]): Captures most variables by value, but y is captured by reference.

```
int x = 10, y = 20;
auto lambda = [=, &y]() { /* ... */ };
```

#### 24.2 Why auto as lambda type

Concept 41: The simplest and most common way is to use auto, which lets the compiler deduce the type of the lambda. This is especially convenient because the actual type of a lambda expression is compiler-generated and cannot be written out explicitly.

# 25 Fancy case syntax

```
int a{5};

switch (a) {
    case 0 ... 9: cout << "in 0-9";
    break;
}</pre>
```

## 26 Static globals

When static is used in the global scope or namespace scope (outside any class), it gives internal linkage to variables or functions. This means that the variable or function is only visible within the translation unit (basically the source file) in which it is declared.

## 27 Classes (OOP Principles in C++)

**Preface** This section will look at the second major programming styles, Object-Oriented programming. In contrast to procedural programming

We create classes in the same fashion in which we create structures

```
class Classname {

// Members
int a;
float b;

// Member functions (methods)
int foo() {

void bar() {

}

the part of th
```

It is very common that the naming of the class conforms to CamelCase in which each words first letter is capitalized

### 27.1 Private and Public (access specifiers)

C++ provides the keywords *private* and *public*, which are known as **access specifies** because they specify how class members may be accessed.

```
class ClassName {
private:
    // Place all private members here

public:
    // Place all public members here

protected:
    // Place all protected members here

// Place all protected members here
```

#### Public:

Public members are accessible from any part of the program where the object is known. That means any client code that has access to an object can access its public data members and member functions directly.

#### Private:

Private members are only accessible from within the class itself. They are not accessible from outside the class, which means you cannot access them using an object of the class from outside the class's member functions or friends.

#### **8** Note:

For classes declared with the **class keyword**, members are private by default. For classes declared with the **struct** keyword, members are public by default.

#### 27.2 Protected

There is also a third access specifier called **protected**. Protected members are similar to private members, but they can also be accessed in derived classes. This is useful when you want to allow a class to inherit the properties of another class, but still keep them from being accessed by the rest of the program.

#### 27.3 Constant member functions

In C++, when you see the const keyword at the end of a member function declaration, it means that the function is a "const member function." This indicates that the function is not allowed to modify any member variables of the class (except those marked as mutable) or call any non-const member functions. Essentially, it guarantees that calling the function will not change the state of the object. To summarize

- Can't modify any member variables (except those marked mutable)
- Can't call any non-const member functions

#### 27.4 The mutable keyword

In C++, the mutable keyword is used to allow a particular member of an object to be modified even if the object is declared as const. Normally, when an object is declared as const, none of its data members can be changed after initialization; they are read-only.

```
class foo {
public:
    mutable int y = 15;

int thing() const {
    y++;
    return y;
}
}
```

### 27.5 The friend keyword

In C++, the friend keyword is used to specify that a function or another class should have access to the private and protected members of the class where the friend declaration is made.

```
class foo {
   private:
2
        int x = 12;
   public:
        friend int thing(foo%);
6
   };
    int thing(foo &obj) {
        ++obj.x;
10
        return obj.x;
11
   }
12
    int main(int argc, const char* argv[]) {
13
14
        foo f1;
15
        cout << thing(f1);</pre>
17
        return EXIT_SUCCESS;
19
   }
```

### 27.6 Member function prototypes and definitions

In C++, it is not necessary for us to define the member functions **inside** the class body. We have the option of writing the prototypes inside the class, but actually defining them **outside** of the class.

```
1  class foo {
2  public:
3    int thing1();
4  };
5
6  int foo::thing1() {
7    return 1;
8  }
```

#### **8** Note:

This would work the same if the prototype was in the **private** access specifier

#### 27.7 Default Constructors

Concept 42: If you do not provide any constructor for your class, C++ compiler generates a default constructor for you. This default constructor does not take any arguments and initializes member variables to their default values (for example, integers to zero).

#### 27.8 Parameterized Constructor

Concept 43: A constructor that takes one or more parameters is known as a parameterized constructor. It is used to initialize the object with specific values.

### 27.9 Copy Constructor

**Concept 44:** A copy constructor is a special constructor that initializes an object using another object of the same class. This is useful for creating a copy of an object.

```
class Rectangle {
   int width, height;
   public:

// Copy constructor
   Rectangle(const Rectangle& other) {
      width = other.width;
      height = other.height;
   }
}
```

#### **8** Note:

The reason we pass by reference is to avoid infinite recursion. When a function parameter in C++ is passed by value, the language's semantics dictate that a copy of the argument is made. You can see how passing by value would lead to a stack overflow

#### 27.10 Constructor Overloading

**Concept 45:** Just like other functions in C++, constructors can also be overloaded. This means you can have more than one constructor in a class, each with a different set of parameters.

#### 27.11 Initialization Lists

**Concept 46:** Constructors can use initialization lists to initialize member variables. This is often more efficient than assigning values in the constructor body.

### 27.12 Delegating Constructors

Concept 47: A constructor can call another constructor of the same class to perform common initialization tasks, reducing code duplication.

```
class Person {
       std::string name;
       int age;
3
   public:
       // Primary constructor
       Person(const std::string& n, int a) : name(n), age(a) {
            std::cout << "Person created: " << name << ", " << age << " years old." <<
       std::endl;
       }
9
       // Delegating constructor
11
       Person() : Person("Unknown", 0) {
            // Additional initialization or operations can be done here if needed
13
       }
14
   };
15
```

#### 27.13 Explicit Constructors

**Concept 48:** By default, C++ allows implicit conversion from a single argument to the type of the class. To prevent this, you can declare a constructor as explicit, which requires explicit conversion.

```
class MyClass {
   public:
       explicit MyClass(int x) {
            // Constructor implementation
   };
   void someFunction(MyClass m) {
       // Function implementation
9
   }
10
11
   int main() {
12
       MyClass obj1(10); // Direct initialization is fine
       // MyClass obj2 = 10; // Error: copy initialization not allowed for explicit
14

→ constructor

15
       someFunction(MyClass(20)); // Direct initialization is fine
        // someFunction(20); // Error: implicit conversion not allowed for explicit
    \hookrightarrow constructor
18
       return 0;
19
   }
20
```

#### 27.14 Destructors

Concept 49: In C++, a destructor is a special member function of a class that is executed when an object of that class is destroyed. Destructors are used to perform any necessary cleanup when an object goes out of scope or is deleted, such as releasing memory, closing files, or freeing other resources.

#### 27.15 Default destructors

**Concept 50:** If you don't define a destructor in your C++ class, the compiler will automatically provide a default destructor for you. This default destructor is sufficient in many cases, especially when your class does not manage any resources that require explicit cleanup (like dynamically allocated memory, file handles, network connections, etc.).

#### 27.16 Accessors and Mutators

Concept 51: Accessors (Getters) and mutators (Setters) are used to control access to the data members of a class. This approach is part of encapsulation, a fundamental principle of object-oriented programming that emphasizes the idea of bundling data and the methods that operate on that data within one unit and restricting direct access to some of the object's components.

```
class MyClass {
   private:
        int myData;
   public:
        // Accessor (Getter)
        int getMyData() const {
            return myData;
        }
10
11
        // Mutator (Setter)
12
        void setMyData(int value) {
13
            myData = value;
14
        }
15
   };
16
```

### 27.17 The "this" pointer

Concept 52: The 'this' pointer in C++ is a special keyword that represents a pointer to the current instance of the class. It is automatically passed as a hidden argument to all non-static member function calls and is available as a local variable within the body of all non-static functions. this is used to refer to the calling object in a member function.

```
class MyClass {
   private:
        int value;
   public:
        MyClass(int value) {
            // Using 'this' to differentiate between the data member and the parameter
            this->value = value;
        }
9
10
        // A function that returns the current object
11
        MyClass* updateValue(int value) {
12
            this->value = value;
            return this; // Returning the current object
14
        }
15
16
        int getValue() const {
17
            return value; // 'this->' is optional here
18
        }
19
   };
20
21
22
   int main(int argc, const char* argv[]) {
23
24
        MyClass* obj = ( new MyClass(5) );
25
26
        obj->updateValue(10)->updateValue(15)->updateValue(20);
27
28
        int val = obj->getValue();
29
        show(val);
31
32
        return 0;
33
34
```

#### 27.18 Static

#### Concept 53:

#### Static Member Variable

A static member variable is shared by all instances of the class. It is not associated with any particular instance of the class but rather with the class itself. There is only one instance of this variable, regardless of how many objects of the class are created.

#### Static member function

Similarly, static member functions are not associated with any particular object of the class. They can only access static members and cannot access non-static members or functions.

#### 27.19 Memberwise assignment

Concept 54: Memberwise assignment refers to the default behavior provided by the compiler when one object of a class is assigned to another. This default assignment operator performs a shallow copy, which means it copies the value of each member of the source object to the corresponding member of the destination object. This is fine for classes that only contain non-pointer data members or for cases where a shallow copy is sufficient. However, if the class contains pointers or dynamic resources, a shallow copy might lead to issues like double deletion or resource leaks.

### 27.20 Aggregation

### 28 Operator Overloading

### 28.1 Overloading arithmetic operators

For binary operators like +, -, \*, etc., if you overload them as member functions, the left operand must be an object of your class, and the right operand is passed as an argument to the operator function.

```
class Vector {
   private:
        int x,y;

   public:
        Vector(int x, int y) : x(x), y(y) {}

        Vector operator+(const Vector& other) const {
            return Vector(x + other.x, y+other.x);
        }
}
```

### 28.2 Overloading Stream Operators

To overload stream operators

```
class Vector {
        private:
2
            int x,y;
3
        public:
            Vector(): x(10), y(15) {}
            Vector(int x, int y) : x(x), y(y) {}
            ~Vector() {
                 cout << "Destroyed object: " << *this << endl;</pre>
            }
        friend std::ostream& operator<<(std::ostream& os, Vector& vc);</pre>
10
        friend std::istream& operator>>(std::istream& is, Vector& vc);
11
   };
12
13
   std::ostream& operator<<(std::ostream& os, Vector& vc) {</pre>
        cout << vc.x << " " << vc.y << endl;
15
        return os;
16
17
   std::istream& operator>>(std::istream& is, Vector& vc) {
        is >> vc.x >> vc.y;
19
20
        return is;
   }
21
22
   int main(int argc, const char* argv[]) {
23
         Vector v1, v2;
24
        cout << "Enter values for Vector v1 (x y): ";</pre>
25
        cin >> v1;
26
        cout << "You entered: " << v1 << endl; return EXIT_SUCCESS; }</pre>
27
```

### 28.3 Overloading Asssignment operator

```
class Vector {
        private:
2
            int x,y;
        public:
4
            Vector(): x(10), y(15) {}
            Vector(int x, int y) : x(x), y(y) {}
6
            Vector& operator=(const Vector& other) {
                if (this != &other) {
                     this->x = other.x;
10
                    this->y = other.y;
12
                cout << "Assignment complete" << endl;</pre>
13
                return *this;
14
            }
15
   };
16
17
   int main(int argc, const char* argv[]) {
        Vector v1{1,2}, v2;
19
        v2 = v1;
20
21
        return EXIT_SUCCESS;
   }
23
```

### 28.4 Overloading Prefix

#### 28.5 Overloading Postfix

#### **8** Note:

Having int as a function parameter is how we distinguish between prefix and postfix.

### 28.6 Overloading Relational Operators

```
bool operator<(const Vector& other) const {</pre>
       return (this->x < other.x) && (this->y < other.y);
2
   }
   bool operator>(const Vector& other) const {
       return (this->x > other.x) && (this->y > other.y);
   bool operator>=(const Vector& other) const {
       return (this->x >= other.x) && (this->y >= other.y);
   }
11
   bool operator<=(const Vector& other) const {</pre>
       return (this->x <= other.x) && (this->y <= other.y);
14
15
16
   bool operator==(const Vector& other) const {
17
       return (this->x == other.x) && (this->y == other.y);
18
   }
19
20
   bool operator!=(const Vector& other) const {
       return (this->x != other.x) && (this->y != other.y);
22
   }
```

#### 28.7 Overloading subscript operator

```
const int& operator[](size_t idx) const {
   return vc[idx];
}
```

### 28.8 Overloading function call operator

```
class Greet {
   private:
        string greeting;
   public:
        Greet(const string& greeting) : greeting(greeting) {}
        void operator()(const string& name) {
            cout << greeting << " " << name << endl;</pre>
        }
   };
10
   int main(int argc, const char* argv[]) {
11
        Greet g1("Hello");
12
        g1("nate");
13
14
        return EXIT_SUCCESS;
15
  }
16
```

#### 28.9 Overloading dereference operator

```
class Resource {
   public:
        void display() const { std::cout << "Displaying Resource" << std::endl; }</pre>
   class SmartPointer {
   private:
        Resource* ptr;
   public:
10
        SmartPointer(Resource* p = nullptr) : ptr(p) {}
        ~SmartPointer() { delete ptr; }
12
        // Overload the dereference operator
14
        Resource& operator*() const { return *ptr; }
   };
16
17
   int main(int argc, const char* argv[]) {
         SmartPointer smartPtr;
19
        (*smartPtr).display(); // Accessing Resource's display metho
20
        return EXIT_SUCCESS;
22
   }
```

#### 28.10 Overloading arrow operator

```
class Resource {
   public:
        void display() const { std::cout << "Displaying Resource" << std::endl; }</pre>
   };
   class SmartPointer {
   private:
       Resource* ptr;
   public:
10
        SmartPointer(Resource* p = nullptr) : ptr(p) {}
11
        ~SmartPointer() { delete ptr; }
12
        // Overload the dereference operator
14
        Resource* operator->() const { return ptr; }
15
   };
16
17
   int main(int argc, const char* argv[]) {
18
         SmartPointer smartPtr;
        smartPtr->display(); // Accessing Resource's display metho
20
        return EXIT_SUCCESS;
22
   }
23
```

### 29 Class Inheritance

**Concept 55:** In C++, it is possible to inherit attributes and methods from one class to another. We group the "inheritance concept" into two categories:

- derived class (child) the class that inherits from another class
- base class (parent) the class being inherited from

To inherit from a class, use the : symbol

```
// Base class
   class Vehicle {
      public:
        string brand = "Ford";
        void honk() {
          cout << "Tuut, tuut! \n" ;</pre>
        }
    };
   // Derived class
   class Car: public Vehicle {
11
      public:
        string model = "Mustang";
13
   };
14
15
    int main() {
16
      Car myCar;
17
      myCar.honk();
18
      cout << myCar.brand + " " + myCar.model;</pre>
19
      return 0;
20
   }
21
```

In c++ we have

- Single Inheritance: A derived class inherits from one base class.
- Multiple Inheritance: A derived class inherits from more than one base class.
- Multilevel Inheritance: A class is derived from a class which is also derived from another class.
- Hierarchical Inheritance: Several derived classes inherit from a single base class.
- **Hybrid Inheritance:** A combination of two or more types of inheritance.

#### 29.1 Access Specifiers

Inheritance can be of three types based on access specifiers: public, protected, or private.

- Public Inheritance (public): Public members of the base class remain public in the derived class, and protected members of the base class remain protected in the derived class.
- Protected Inheritance (protected): Public and protected members of the base class become protected in the derived class.
- Private Inheritance (private): Public and protected members of the base class become private in the derived class.

#### 29.2 Constructors and Destructors

#### Concept 56:

- Constructors and destructors are not inherited. However, when you create an object of a derived class, its constructor calls the constructor of the base class. You can also specify which base class constructor should be called using an initializer list.
- The destructor of the base class is called automatically when the derived class object is destroyed.

#### 29.3 Virtual functions and the override keyword

Concept 57: In C++, the virtual keyword is used primarily in base classes to ensure that the correct member functions are called on objects of derived classes, even when they are referred to with base class pointers or references. This is a key part of implementing polymorphism in C++.

```
#include <iostream>
2
    class Base {
    public:
        virtual void show() {
             std::cout << "Base class show function called." << std::endl;</pre>
6
        }
    };
    class Derived : public Base {
10
    public:
11
        void show() override {
12
             std::cout << "Derived class show function called." << std::endl;</pre>
13
        }
14
   };
15
16
    int main() {
17
        Base *bptr;
18
        Derived d;
19
        bptr = &d;
21
        // Virtual function, binded at runtime (Runtime polymorphism)
22
        bptr->show();
23
24
        return 0;
25
   }
```

#### 29.4 Virtual Destructors

Concept 58: Virtual destructors are important when you deal with inheritance and dynamic memory allocation. If a base class destructor is not virtual, deleting an instance of a derived class via a pointer to the base class leads to undefined behavior (typically, it results in a memory leak).

#### 29.5 Base class pointer to child class object

The primary reason for using base class pointers (or references) to point to derived class objects is to achieve polymorphic behavior. When you have a hierarchy of classes with virtual functions, you can use a base class pointer to work with objects of any derived class without knowing their exact type.

```
Class Animal {
   public:
        virtual void speak() = 0; // Pure virtual function
   };
    class Dog : public Animal {
   public:
        void speak() override { std::cout << "Woof!" << std::endl; }</pre>
   };
9
10
    class Cat : public Animal {
11
    public:
12
        void speak() override { std::cout << "Meow!" << std::endl; }</pre>
   };
14
15
   void makeAnimalSpeak(Animal* animal) {
16
        animal->speak();
17
   }
18
19
    int main() {
20
        Dog dog;
21
        Cat cat;
22
23
        makeAnimalSpeak(&dog); // Outputs: Woof!
24
        makeAnimalSpeak(&cat); // Outputs: Meow!
25
   }
26
```

### 30 Interface-Based Programming

Concept 59: Interface-based programming is a software design principle that emphasizes the use of interfaces for defining the behavior that classes must implement. In languages like Java or C#, an interface is a formal construct that defines a contract in the form of methods that a class must implement. However, C++ does not have a direct interface keyword or construct like those languages. Instead, C++ uses abstract classes, particularly pure abstract classes, to achieve a similar effect.

#### 30.1 Pure Abstract Classes in C++

In C++, an interface is typically represented by a class where all member functions are pure virtual functions. Such a class is often referred to as a "pure abstract class." A pure virtual function is declared by assigning 0 to the function declaration in the class definition.

```
class IShape {
  public:
    virtual ~IShape() {} // Virtual destructor

    virtual void draw() const = 0; // Pure virtual function
    virtual double area() const = 0; // Pure virtual function
};
```

### 30.2 Implementing Interfaces in C++

A concrete class implements the interface by inheriting from the pure abstract class and providing implementations for the pure virtual functions:

```
class Circle : public IShape {
   public:
        Circle(double radius) : radius(radius) {}
        void draw() const override {
            // Implementation of drawing a circle
        }
        double area() const override {
            return 3.14159 * radius * radius;
10
       }
11
12
   private:
13
       double radius;
14
   };
15
```

### 30.3 More on the concept of pure virtual functions

**Concept 60:** In C++, assigning zero to a member function declaration within a class definition is how you declare a pure virtual function. This is a key concept in creating abstract classes and interfaces in C++.

A pure virtual function is a function that must be overridden in any concrete (non-abstract) subclass. It's a way to enforce that certain functions are implemented in derived classes. By declaring a function as pure virtual, you're essentially saying that the base class provides no meaningful implementation for this function, and it's the responsibility of each derived class to provide its own implementation.

## 31 Separate files (Classes)

**Concept 61:** Splitting up classes among multiple files in C++ is a common practice for organizing code, especially in large projects. It helps in managing the codebase, making it more readable, maintainable, and scalable. Here's a basic guide on how to do it:

#### 31.1 Class declaration in Header Files

• **Header File:** Contains the class declaration. This includes member variables, function prototypes, and any necessary includes or other class declarations.

#### myclass.h

```
#ifndef MYCLASS_H
#define MYCLASS_H

class MyClass {
  public:
    MyClass(); // Constructor
    void myFunction(); // A member function

private:
    int myVariable; // A member variable
};

#endif // MYCLASS_H
```

#### 31.2 Class Definition in Source Files

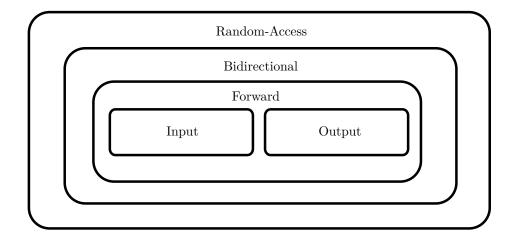

## 31.3 Exceptions

# 32 Rvalue references and move semantics

Concept 62:

### 33 Iterators

Concept 63: All iterators do not have similar functionality as that of pointers. Depending upon the functionality of iterators they can be classified into five categories, as shown in the diagram below with the outer one being the most powerful one and consequently the inner one is the least powerful in terms of functionality.

### 33.1 Type of Iterators

- **Input Iterators:** They are the weakest of all the iterators and have very limited functionality. They can only be used in a single-pass algorithms, i.e., those algorithms which process the container sequentially, such that no element is accessed more than once.
- Output Iterators: Just like input iterators, they are also very limited in their functionality and can only be used in single-pass algorithm, but not for accessing elements, but for being assigned elements.
- Forward Iterator: They are higher in the hierarchy than input and output iterators, and contain all the features present in these two iterators. But, as the name suggests, they also can only move in a forward direction and that too one step at a time.
- **Bidirectional Iterators:** They have all the features of forward iterators along with the fact that they overcome the drawback of forward iterators, as they can move in both the directions, that is why their name is bidirectional.
- Random-Access Iterators: They are the most powerful iterators. They are not limited to moving sequentially, as their name suggests, they can randomly access any element inside the container. They are the ones whose functionality are same as pointers.

ITERATORS	PROPERTIES				
	ACCESS	READ	WRITE	ITERATE	COMPARE
Input	->	= *i		++	==, !=
Output			*i=	++	
Forward	->	= *i	*i=	++	==, !=
Bidirectional		= *i	*i=	++,	==, !=,
Random-Access	->,[]	= *i	*i=	++,, +=, -==, + ,-	==, !=, <,>,<=,>=

#### 33.2 Container Iterators

- std::vector<T>::iterator: RandomAccess
- std::array<T, N>::iterator: RandomAccess
- std::list<T>::iterator: Bidirectional
- std::set<T>::iterator: Bidirectional
- std::map<Key, T>::iterator: Bidirectional

```
std::vector<int> vc{1,2,3};
std::vector<int>::iterator it;
for (it = vc.begin(); it != vc.end(); ++it)
```

### 33.3 What about C-Array

When we do something of the nature

```
int arr[] {1,2,3};
for (auto it=std::begin(arr); it != std::end(arr); ++i) { }
```

The type of iterator we get is essential just a pointer that acts as a Randomaccess iterator
